Graph Structures

1.1 Multigraphs

Intuitively, we would describe a *graph* as a collection of nodes (or vertices) plus some lines (or edges) joining some nodes together. This can be rigorously defined as follows:

Definition 1.1.1 ► Multigraph

A **multigraph** G consists of a non-empty finite set of vertices denoted by $V(G)$ and a finite set of edges denoted by $E(G)$. $|V(G)|$ is known as the **order** of G , denoted by $v(G)$ and $|E(G)|$ is known as the **size** of G , denoted by $e(G)$. In particular, if $v(G) = m$ and $e(G) = n$, we say that G is an **(m, n) -graph**. G is said to be **trivial** if $v(G) = 1$ and **non-trivial** otherwise.

Note that in a multigraph, by default there can be a plural number of edges between any two vertices. We would define the notion of *simple graph* as a special multigraph.

Definition 1.1.2 ► Simple Graph

A multigraph G is said to be **simple** if there is at most one edge between any two distinct vertices.

Remark. Note that if G is simple and undirected, then

$$E(G) \subseteq \{(v_j, v_i) : v_j, v_i \in V(G), j \geq i\}.$$

Notice that if (v_i, v_i) is an edge, it connects a vertex to itself. This is known as a *loop*.

In a graph, it is important to know the layout of the vertices and edges. For this purpose, we define the notion of *adjacency* in a multigraph.

Definition 1.1.3 ► Adjacency and Neighbourhood

Let $v_i, v_j \in V(G)$, we say that they are **adjacent** if $v_i v_j \in E(G)$. Alternatively, we say that v_i and v_j are **neighbours** to each other. The edge $v_i v_j$ is said to be **incident** with v_i and v_j . Two edges e and f are said to be **adjacent** if there exists some $v \in V(G)$ such that both e and f are incident with v .

The set of all neighbours to some $v_i \in V(G)$ is called the **neighbourhood set** of v_i , denoted by $N_G(v_i)$. In particular, the set $N_G[v_i] := N_G(v_i) \cup \{v_i\}$ is known as the **closed neighbourhood set** of v_i .

Alternatively, one may write $v \sim u$ if v and u are adjacent vertices. We can further add on to the definition by discussing the size of the neighbourhood of a vertex.

Definition 1.1.4 ► Degree

The **degree** of v , denoted by $d_G(v)$ is defined as the number of edges incident to v . If $d_G(v)$ is even (repectively, odd), then we say that v is an even (respectively, odd) vertex. If $d_G(v) = 0$, we say that v is **isolated**; if $d_G(v) = 1$, we say that v is an **end** vertex. In particular, we define

$$\Delta(G) = \max_{v \in G} d_G(v), \quad \delta(G) = \min_{v \in G} d_G(v).$$

In particular, we can denote the average degree of a graph G by

$$\bar{d}(G) = \frac{\sum_{v \in V(G)} d_G(v)}{v(G)}.$$

Remark. Note that a high maximal degree does not imply a high average degree. A classic counter example is a complete graph plus an isolated vertex.

With the notion of degree established, we can now define a *regular graph*.

Definition 1.1.5 ► Regular Graph

A **regular graph** is a graph in which every vertex has the same degree. In particular, if $d_G(v) = k$ for all $v \in V(G)$, G is known as a **k -regular graph**.

Remark. A graph G is regular if and only if $\Delta(G) = \delta(G)$.

Since a graph essentially consists of two sets, it is natural to consider the notion of graph complementation. We now proceed to introducing the notion of *complement*.

Definition 1.1.6 ► Complement

Let G be a graph of order n , the **complement** of G , denoted by \bar{G} , is the graph of order n where

$$V(\bar{G}) = V(G), \quad E(\bar{G}) = \{(u, v) : (u, v) \notin E(G)\}.$$

We discuss the following interesting question:

15 students went to a party. During the party some of them shook hands with each other. At the end of the party, the total number of handshakes made by all student was to be 39. Was this possible?

Note that if we represent each student as a vertex, then we can use $V(G) = \{v_1, v_2, \dots, v_{15}\}$ to construct a graph, in which an edge $v_i v_j \in E(G)$ if and only if students i and j shook hands. As such, $d_G(v_i)$ is the number of persons student i shook hands with.

Note that if we sum up $d_G(v_i)$ for all the vertices, every edge will be counted exactly twice! This means that $\sum_{i=1}^{15} d_G(v_i) = 39$ is impossible since the left-hand side must be even. In fact, we see that in any graph, the sum of degrees of its vertices must be even.

Lemma 1.1.7 ► Handshaking Lemma

If G is a graph of order n and size m , then

$$\sum_{i=1}^n d_G(v_i) = 2m.$$

Remark. It can be easily deduced from the above lemma that in any graph, the number of vertices with odd degrees must be even.

Observing Definition 1.1.4, we see that the average degree of a graph G can be computed as

$$\bar{d}(G) = \frac{2e(G)}{v(G)}.$$

As an extension of Lemma 1.1.7, the minimum size of any graph is obviously 0, and the maximum size of a simple graph occurs when there is an edge between any two vertices.

Definition 1.1.8 ► Empty and Complete Graphs

Let G be a simple graph of order n . G is said to be an **empty graph** or **null graph**, denoted by 0_n , if $e(G) = 0$, and a **complete graph**, denoted by K_n if for all $u, v \in V(G)$, we have $(u, v) \in E(G)$.

Since a multigraph is just two sets, we can define a “subset” relation between graphs.

Definition 1.1.9 ► Subgraph

Let G, H be graphs, then H is a **subgraph** of G if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. In particular, a subgraph H is a **proper subgraph** of G if $V(H) \neq V(G)$ or $E(H) \neq E(G)$.

Note that we a graph can possibly be reproduced by connecting its vertices correctly, so a subgraph containing all vertices of a graph “spans” the original graph.

Definition 1.1.10 ► Spanning Subgraph

Let H be a subgraph of G . H is called a **spanning subgraph** of G if $V(H) = V(G)$.

Note that by definition, a spanning subgraph retains all vertices of the original graph. Therefore, a way to quickly generate a subgraph of a given graph G is to keep the vertex set and delete some edges from the edge set. We denote such a graph by $H = G - F$ for some $F \subset E(G)$. Observe that

$$V(H) = V(G), \quad E(H) = E(G) - F.$$

On the other hand, by deleting some vertices together with edges incident to them, we can produce a subgraph from any given graph.

Definition 1.1.11 ► Induced Subgraph

Let H be a subgraph of G . H is called a **induced subgraph** of G if

$$E(H) = \{uv \in E(G) : u, v \in V(H)\}.$$

Let $S \subseteq V(G)$, the subgraph of G induced by S is denoted by $[S]$.

Alternatively, let $F \subseteq E(G)$. Define

$$V' := \bigcup \{u, v\} : uv \in F,$$

then (V', F) is the subgraph of G induced by F , denoted by $G[F]$.

Intuitively, an induced subgraph pf G consists of a selected subset of the vertices of G together with all edges in G connecting any vertices in this subset.

Using the idea of deletion, we can quickly generate an induced subgraph H of G as follows: first, set $V(H) = V(G) - A$ for some $A \subseteq V(G)$, i.e., remove some vertices; then, we will remove all edges from $E(G)$ which are incident to some vertices in A , i.e., set

$$E(H) = \{e \in E(G) : e \text{ is not incident to any } v \in A\}.$$

Then, $H = (V(H), E(H))$ is an induced subgraph of G . In fact, we can denote H as

$$H = G - A = [V(G) - A].$$

This leads to the following proposition:

Proposition 1.1.12 ▶ Alternative Definition of Induced Subgraph

Let G be a graph. If $A \subseteq V(G)$, then $G - A = [V(G) - A]$. Suppose H is a subgraph of G , then H is an induced subgraph of G if and only if $H = G - (V(G) - V(H))$.

We would like to consider the relations between the properties of a graph to those of its subgraphs. In particular, it follows from intuition that if a graph has a high average degree, then we can naturally find a subgraph with a high minimal degree.

This seems trivial from intuition, as we can always keep deleting vertices with the minimal degree from a graph until we cannot find any vertex whose degree is less than $\frac{1}{2}\bar{d}(G)$, but there is more to that — for instance, how do we know if we would not end up deleting all vertices from the original graph? Thus, to prove our claim is essentially asking to prove the correctness of this greedy deletion, which we shall do in the following proposition.

Proposition 1.1.13 ▶ Subgraphs with High Minimum Degree

Every non-empty graph G has a subgraph H such that $\delta(H) \geq \frac{1}{2}\bar{d}(G)$.

Proof. Define $H_0 = G$ and $H_{i+1} = H_i - v_i$ where v_i is a vertex in H_i whose degree is the smallest. Note that we can always find this v_i for any H_i with $V(H_i) \neq \emptyset$ because $V(H_i)$ is a finite well-ordered set. We will repeatedly perform the deletion until we obtain some H_k with $d_{H_k}(v_k) \geq \frac{1}{2}\bar{d}(G)$. We shall proceed to proving that this algorithm always terminates with $V(H_k) \neq \emptyset$.

Suppose on contrary that $V(H_k) = \emptyset$, then we have performed the deletion for $v(G)$ times. Suppose we have deleted N edges in total, then clearly,

$$N < v(G)\frac{1}{2}\bar{d}(G) = v(G)\frac{e(G)}{v(G)} = e(G),$$

which means $e(H_k) = e(G) - N > 0$. However, this is impossible since $v(H_k) = 0$, which is a contradiction. \square

Given two graphs G and H , are they the same graph? This seemingly innocent question proves to be extremely hard to answer. Two graphs can look drastically different but be structurally identical in reality. For example, we could shift around the vertices of a graph without changing any edge to alter the shape of the graph dramatically. Therefore, to compare the structures of graphs, we require some rigorous definition.

Definition 1.1.14 ▶ Graph Isomorphism

Two graphs G and H are said to be **isomorphic**, denoted by $G \cong H$, if there exists a bijection $f : V(G) \rightarrow V(H)$ such that

$$uv \in E(G) \quad \text{if and only if} \quad f(u)f(v) \in E(H).$$

Remark. Graph isomorphism is obviously an equivalence relation.

Such a bijection f is said to **preserve adjacency**, i.e., if u and v are neighbours in G , then their images are also neighbours in H . In particular, it is possible to map a graph to its own complement via an isomorphism.

Definition 1.1.15 ▶ Self-Complementary Graph

A graph G is said to be **self-complementary** if $G \cong \overline{G}$.

It turns out that a self-complementary graph satisfies some special properties.

Proposition 1.1.16 ▶ Order of Self-Complementary Graphs

If G is a self-complementary graph of order n , then either $n = 4k$ or $n = 4k + 1$ for some $k \in \mathbb{Z}^+$.

Proof. Since G is self-complementary, $G \cong \overline{G}$ and so $e(G) = e(\overline{G})$. Note that

$$e(G) + e(\overline{G}) = \binom{n}{2} = \frac{n(n-1)}{2},$$

so we have $e(G) = \frac{n(n-1)}{4}$. Since $e(G) \in \mathbb{Z}^+$, either n or $n-1$ is divisible by 4, so $n = 4k$ or $n = 4k + 1$ for some $k \in \mathbb{Z}^+$. □

It is very hard to determine whether two specific graphs are isomorphic, but there are some considerations in the general case. For example, some trivial conclusions include:

- Two graphs with different orders cannot be isomorphic.
- Two graphs with different sizes cannot be isomorphic.
- Two graphs with different numbers of components cannot be isomorphic.
- If the numbers of vertices with degree k are different in two graphs, they cannot be isomorphic.

Notice that by Definition 1.1.14, we can define a function g such that $uv \notin E(G)$ if and only

if $g(u)g(v) \notin E(H)$ and relate this function to the complement graphs of G and H . Here we introduce a way to determine isomorphism by considering complement graphs, the proof of which is left to the reader as an exercise.

Theorem 1.1.17 ► Complementations Preserves Isomorphism

Let G and H be two graphs of the same order. $G \cong H$ if and only if $\overline{G} \cong \overline{H}$.

Now let us think the reverse: if it is not easy to prove isomorphism, can we find a way to quickly determine that two graphs are not isomorphic? Here we present the necessary conditions for isomorphism:

Theorem 1.1.18 ► Necessary Conditions for Isomorphism

If $G \cong H$, then

1. *G and H must have the same order and size.*
2. *$\delta(G) = \delta(H)$ and $\Delta(G) = \Delta(H)$.*
3. *The number of vertices with degree i in G and H is the same for all $i \in \mathbb{N}$.*

The first two conditions are easy to observe. For the third condition, we introduce a tool known as *degree sequences*.

Definition 1.1.19 ► Degree Sequence

Let G be a graph of order n . If we label its vertices by v_1, v_2, \dots, v_n such that

$$d(v_1) \geq d(v_2) \geq \dots \geq d(v_n),$$

then the non-increasing sequence $(d(v_n))$ is known as the **degree sequence** of G .

Now we consider the following question:

Let (d_n) be a non-increasing sequence, is there some graph whose degree sequence is (d_n) ?

We will make use of the following definition:

Definition 1.1.20 ► Graphic Sequence

Let (d_n) be a sequence of non-negative integers at most $n-1$. (d_n) is said to be **graphic** if there exists a graph G whose degree sequence is (d_n) .

To determine whether a sequence is graphic by eye power is difficult. Fortunately, we have the following recursive algorithm:

Theorem 1.1.21 ► Havel-Hakimi Algorithm

Let (d_n) be a non-increasing sequence of non-negative integers at most $n - 1$. Define

$$d_m^* = \begin{cases} d_{m+1} - 1 & \text{if } 1 \leq m \leq d_1 \\ d_{m+1} & \text{if } d_1 + 1 \leq m \leq n - 1 \end{cases}.$$

(d_n) is graphic if and only if (d_m^*) is graphic.

Proof. Suppose (d_n) is graphic, we consider the following lemma:

Lemma 1.1.22

For any graphic sequence (d_n) , there is some graph G of order n with $d_G(v_i) = d_i$ for $i = 1, 2, \dots, n$ such that v_1 is adjacent to v_j for $j = 2, 3, \dots, d_1 + 1$.

Proof. Suppose on contrary there is no such a graph G , then for any graph G with degree sequence (d_n) , v_1 is adjacent to at most $d_1 - 1$ vertices in

$$A := \{v_j : j = 2, 3, \dots, d_1 + 1\}.$$

Thus, there exists some $v_j \in A$ such that $v_1 v_j \notin E(G)$. However, $d_G(v_1) = d_1$, so there exists some $v_k \in V(G) - A$ with $v_k \neq v_1$ such that $v_1 v_k \in E(G)$.

Notice that since $v_k \notin A \cup \{v_1\}$, $k > j$ and so $d_G(v_k) = d_k \leq d_j = d_G(v_j)$. Therefore, v_j has at least as many neighbours as v_k , which means there must exist some v_r with $v_j v_r \in E(G)$ such that $v_k v_r \notin E(G)$.

Define a graph G' by

$$V(G') = V(G), \quad E(G') = E(G) - v_j v_r - v_1 v_k + v_j v_k + v_1 v_j.$$

Note that $d_{G'}(v_i) = d_G(v_i)$ for all $i = 1, 2, \dots, n$, so (d_n) is also a degree sequence for G' . However, now v_1 in G' is adjacent to all vertices in A , which is a contradiction. \square

By Lemma 1.1.22, we can choose some graph G whose degree sequence is (d_n) such that v_1 is adjacent to d_1 vertices $v_2, v_3, \dots, v_{d_1+1}$. Let $H = G - v_1$, then for any $u_i \in H$,

$$d_H(u_i) = \begin{cases} d_G(v_{i+1}) - 1 & \text{if } 1 \leq i \leq d_1 \\ d_G(v_{i+1}) & \text{if } d_1 + 1 \leq i \leq n - 1 \end{cases}.$$

Therefore, (d_m^*) is graphic.

Conversely, suppose (d_m^*) is graphic, then there is some graph H of order $n - 1$ such that $d_H(u_i) = d_i^*$ for $i = 1, 2, \dots, d_1$. Construct a graph $G = H + v_1$ such that $v_i = u_{i-1}$ for $i = 2, 3, \dots, n$ and v_1 is adjacent to $v_2, v_3, \dots, v_{d_1+1}$. Therefore,

$$d_G(v_i) = \begin{cases} d_1 & \text{if } i = 1 \\ d_{i-1}^* + 1 & \text{if } 2 \leq i \leq d_1 + 1 \\ d_i^* & \text{if } d_1 + 2 \leq i \leq n \end{cases}$$

Note that $d_G(v_i) = d_i$, so (d_n) is graphic. □

By Theorem 1.1.21, we can reduce a sequence recursively until we reach some obvious case. This obvious case is graphic if and only if the original sequence is graphic. We can also build the graph corresponding to the original sequence from a simple graphic sequence.

Alternatively, the following is another algorithmic way to determine whether a sequence is graphic.

Theorem 1.1.23 ► Erdos-Gallai Algorithm

A non-increasing sequence (d_1, d_2, \dots, d_n) is graphic if and only if $\sum_{i=1}^n d_i$ is even and for all $k = 1, 2, \dots, n$,

$$\sum_{i=1}^k d_i \leq k(k-1) + \sum_{i=k+1}^n \min\{d_i, k\}.$$

We will not give the full proof but only briefly justify the “only if” direction. Let G be any graph. Define $d_i = d_G(v_i)$ where $v_i \in V(G)$ for $i = 1, 2, \dots, n$, then (d_1, d_2, \dots, d_n) is graphic. Note that $\sum_{i=1}^n d_i$ is obviously even by Lemma 1.1.7.

Take some $k \in \mathbb{Z}^+$ with $k \leq n$ and let $S = \{v_1, v_2, \dots, v_k\}$, then by Lemma 1.1.7 again,

$$\begin{aligned} \sum_{i=1}^k d_i &= 2e(G[S]) + e_G(S, V(G) - S) \\ &\leq k(k-1) + e_G(S, V(G) - S), \end{aligned}$$

where $e_G(S, V(G) - S)$ is the number of edges in G which connect a vertex in S to a vertex

in $V(G) - S$. Notice that

$$e_G(S, V(G) - S) = \sum_{i=k+1}^n |\{u \in S : uv_i \in E(G)\}|$$

$$\sum_{i=k+1}^n \leq \min\{k, d_i\},$$

and so it follows that

$$\sum_{i=1}^k d_i \leq k(k-1) + \sum_{i=k+1}^n \min\{d_i, k\}.$$

Remark. Both Theorems 1.1.21 and 1.1.23 are $\mathcal{O}(n^2)$ algorithms.

1.2 Graph Traversal

We are often interested in the “connectedness” in a graph. In particular, we would wish to study how to traverse a graph from some vertices to others.

Definition 1.2.1 ► Walk, Trail, Path

Let G be a graph and $x, y \in V(G)$, then an **x-y walk** is an alternating sequence

$$W := v_0 e_1 v_1 e_2 v_2 \cdots v_{n-1} e_n v_n$$

where $v_i \in V(G)$, $e_i = v_{i-1}v_i \in E(G)$, $x = v_0$ and $y = v_n$. In particular, W is **open** if $v_0 \neq v_n$ and **closed** otherwise. The **length** of a walk is defined as the number of edges in it.

If $e_i \neq e_j$ whenever $i \neq j$, then W is called a **trail**. A closed trail is called a **circuit**. If $v_i \neq v_j$ whenever $i \neq j$, then W is called a **path**. A closed path is called a **cycle**.

Remark. All paths are trails and all trails are walks, but the converses are not true.

In more informal terms, a trail is a walk with no repeated edge and a path is a trail with no repeated vertex.

Note that a path is essentially a graph. We denote a path of order n by P_n and a cycle of order n by C_n . It is easy to see that all cycles are circuits and all circuits are all closed walks, but the converses are not true. However, if we have a circuit, we can guarantee that this circuit contains at least one cycle.

Intuitively, all walks can be reduced to a path by removing duplicated edges and vertices repeatedly.

Proposition 1.2.2 ► Any Walk Contains A Path

If a graph G contains a u - v walk of length k , then G contains a u - v path of length at most k .

Proof. Let S be the set of all u - v walks in G . Note that $S \neq \emptyset$ since there is a u - v walk of length k . Let P be a walk of the shortest length. We claim that P must be a path.

Suppose P is not a path, then there exists some vertices $w_1 = w_2$ in P . Suppose Q is obtained by removing the w_1 - w_2 walk from P , then Q is a walk. However, Q is shorter than P which is not possible. Therefore, P must be a path.

Note that the length of P is at most k , so G contains a u - v path of length at most k . □

We also have the following relevant definitions with regard to cycles:

Definition 1.2.3 ► Girth and Circumference

Let G be a graph. The **girth** of G is the size of the shortest non-trivial cycle in G and the **circumference** of G is the size of the longest non-trivial cycle in G .

If G is acyclic, we define the girth of G to be ∞ and the circumference to be 0. In some special graphs, we realise that we can traverse through every vertex and return to the starting point in a single traversal. Such graphs are said to be *Hamiltonian*.

An important question we are interested in with graphs is the reachability of a vertex, i.e., given two vertices u and v , we want to know whether we can reach one vertex from another. Intuitively, we can traverse between two vertices if there is a path between them. From here we define the notion of a *connected graph*.

Definition 1.2.4 ► Connected Graph

Let G be a graph. Two vertices u and v are **connected** if there is a path between them. G is said to be **connected** if for any $u, v \in V(G)$, there exists a path from u to v . For any $u \in V(G)$, we denote the set of all vertices connected to u (inclusive of u) as $c(u)$.

Intuitively, we of course always can find a connected subgraph of a connected graph, but we can in fact produce a much stronger result.

Proposition 1.2.5 ▶ Labelling of Vertices of Connected Graphs

For every connected graph G , $V(G)$ can be labelled as $\{v_1, v_2, \dots, v_n\}$ such that the graph $G_i := [\{v_1, v_2, \dots, v_i\}]$ is connected for every $i = 1, 2, \dots, n$.

Proof. For $i = 1$, we can pick any vertex in $V(G)$ as v_1 and G_1 is always trivially connected.

Suppose we have fixed up to k vertices for some $k = 1, 2, \dots, n-1$, then G_1, G_2, \dots, G_k are connected subgraphs of G . Note that $v(G) = n > k$, so there exists some $v \in V(G) - V(G_k)$ such that v and v_1 are connected by a path P . Note that there exists some $u \in V(P)$ such that $u \sim v$ for some $v \in V(G_k)$, so taking $v_{k+1} = u$ guarantees that G_{k+1} is connected. \square

Intuitively, if a graph has many edges, we would believe that it is easy to find a long path in it. Note that the notion of “having many edges” can be related to the minimal degree of a graph. More formally, the following result is true:

Proposition 1.2.6 ▶ Finding Paths and Cycles in Graphs

Every graph G with $\delta(G) \geq 2$ contains a path of length $\delta(G)$ and a cycle of length at least $\delta(G) + 1$.

Proof. Let $P = x_0x_1 \dots x_k$ be the longest path in G . Note that it suffices to prove that $k \geq \delta(G)$. Suppose that there exists some $v \in N(x_k)$ such that $v \notin V(P)$, then we can find a longer path which is not possible. Therefore, $N(x_k) \subseteq V(P)$. Note that $|N(x_k)| \geq \delta(G)$, so $k \geq \delta(G)$ and so G contains a $P_{\delta(G)} \subseteq P$.

Let $i \in \mathbb{N}$ be such that $x_jx_k \notin E(G)$ for all $0 \leq j < i$. Take $P' = x_ix_{i+1} \dots x_k$, then $e(P') \geq \delta(G)$ by the previous argument. However, $x_i \sim x_k$, so $P' + x_ix_k$ is a cycle of length at least $\delta(G) + 1$ in G . \square

Note that connectedness is an equivalence relation. Let P be a partition formed by the equivalence classes of G under the connectedness relation, then for any $u, v \in V(G)$, u and v are in the same equivalence class if and only if u and v are connected. Any $c(u) \in P$ induces a subgraph $[c(u)]$.

Definition 1.2.7 ▶ Connected Component

Let G be a graph and R be a relation such that for any $u, v \in V(G)$, uRv if and only

if u and v are connected. Let

$$C := V(G)/R$$

be the quotient set, then any $c(u) \in C$ is known as a (connected) **component** of G .

The number of components of G is denoted by $\omega(G)$.

Alternatively, a connected component is a maximally connected subgraph, that is, a connected component of G is a subgraph $H \subseteq G$ such that for all $e \in E(G)$, $H + e$ is not connected and for all $v \in V(G) - V(H)$, $[V(H) \cup \{v\}]$ is not connected.

It can be easily seen that G is connected if and only if $\omega(G) = 1$.

We will now establish a relationship between connectedness and complementation.

Theorem 1.2.8 ► Connectedness of Complement

If G is disconnected, then \overline{G} is connected.

Proof. Let $u, v \in V(\overline{G})$ be two arbitrary vertices. If $uv \notin E(G)$, then $uv \in \overline{G}$ and so u and v are connected in \overline{G} .

If $uv \in E(G)$, since G is disconnected, there exists some $w \in V(G)$ such that $uw, vw \notin E(G)$. Therefore, $uw, vw \in \overline{G}$. This means that there is a u - v path in \overline{G} and so u and v are connected in \overline{G} .

Therefore, \overline{G} is connected. □

Intuitively, we can transform a connected graph into a disconnected one by deleting some vertices or edges. It can be easily observed that in certain graphs, deleting one particular vertex or edge will immediately disconnect the graph.

Definition 1.2.9 ► Cut-Vertex, Bridge

Let G be a non-trivial graph. $v \in V(G)$ is called a **cut-vertex** of G if $\omega(G - v) > \omega(G)$.
 $e \in E(G)$ is called a **bridge** of G if $\omega(G - e) > \omega(G)$.

Note that a graph does not have to be connected to have cut vertices and bridges. Essentially, a cut-vertex (or bridge) is just a vertex (or edge) which disconnects a component upon removal.

Now the next question is how do we identify a cut-vertex or a bridge in a graph? Intuitively, a cut-vertex divides a graph into two portions such that traversal between the two portions

has to pass through it.

Theorem 1.2.10 ► Cut-Vertex Characterisation

Let G be a graph. $v \in V(G)$ is a cut-vertex if and only if there exists $a, b \in V(G)$ such that v is in every path between a and b .

Proof. Let $v \in V(G)$ be a cut-vertex and consider $H = G - v$, then we can find two non-empty disjoint connected components of H , say H_1 and H_2 . Now, take $a \in V(H_1)$ and $b \in V(H_2)$, then they are disconnected. However, a and b are connected in G , which means v is in every a - b path.

We will prove the converse by contrapositive. Suppose v is not a cut-vertex of G , then $G - v$ is connected. Therefore, for any $u, w \in V(G)$, there is a path between them which does not contain v . □

A similar argument can be established for bridges. Furthermore, since we have to pass through the bridge when traversing between the two portions, it can be easily seen that we have to reuse the bridge in order to traverse back.

Theorem 1.2.11 ► Bridge Characterisation

Let G be a graph. $e \in E(G)$ is a bridge if and only if e is not contained by any cycle in G .

Proof. We will prove the forward direction by contrapositive. Suppose $e = xy$ is contained in some cycle in G , then there is some x - y path in $G - e$. Suppose $a, b \in V(G)$ are connected in G via a path containing e , this implies that there is some a - b path in $G - e$ and so $G - e$ is connected, which means that e is not a bridge.

We will prove the converse also by contrapositive. Suppose $e = xy$ is not a bridge, the $G - e$ is connected and so there is some x - y path in $G - e$. Let this path be P , then $P \cup \{e\}$ is a cycle in G . □

Combining the two characterisations, we can relate cut-vertices to bridges in the following proposition, the proof of which is left to the reader as an exercise:

Proposition 1.2.12

Let G be a graph. If $uv \in E(G)$ is a bridge and u is not an end vertex, then u is a cut-vertex.

A direct consequence of this is the following corollary:

Corollary 1.2.13

If G is a graph with order at least 3 and G contains a bridge, then G contains a cut-vertex.

Given a graph G with u, v being two connected vertices, we are interested in the notion of distance between them. Intuitively, if there are multiple paths between u and v , we would take the length of the shortest one to represent their distance.

Definition 1.2.14 ► Distance, Eccentricity, Diameter

Let G be a connected graph and let $u, v \in V(G)$. The **distance** between u and v , denoted by $d(u, v)$, is the length of the shortest path between u and v . The **eccentricity** of u is defined to be

$$e(u) = \max_{v \in V(G)} \{d(u, v)\}.$$

The **diameter** of G is defined by

$$\text{diam}(G) = \max_{u \in V(G)} \{e(u)\}.$$

The **radius** of G is defined by

$$\text{rad}(G) = \min_{u \in V(G)} \{e(u)\}.$$

A vertex v is called a **central** vertex if

$$e(v) = \text{rad}(G).$$

The subgraph induced by the set of central vertices of G is known as the **centre** of G .

This also justifies the use of words “diameter” and “radius” in a circle. We can view a circle as a graph consisting of a centre and infinitely many vertices in the circumference, with edges of length r connecting the centre to the circumference. Indeed, in this definition, the farthest vertices will be any two on the circumference with a distance of $2r$, and the nearest vertices will be the centre and any vertex on the circumference with a distance of r .

Intuitively, having a large diameter means that the graph is sparse, i.e., one has to take a very long path to traverse between two vertices. Now let us consider a connected but sparse graph, the above intuition means that we may expect to find that the cycles in this graph are very large.

Proposition 1.2.15 ▶ Graphs with High Girth Have High Diameter

Let G be a graph with girth $g(G)$. If G contains a cycle, then $g(G) \leq 2\text{diam}(G) + 1$.

Proof. Suppose on contrary that $g(G) \geq 2\text{diam}(G) + 2$. Let $C \subseteq G$ be the shortest cycle in G , then we can take $x, y \in V(C)$ such that $d_C(x, y)$ is the greatest. Clearly, we have $d_C(x, y) \geq \text{diam}(G) + 1$.

By Definition 1.2.14, there exists some path P between x and y with $e(P) \leq \text{diam}(G)$. Let $P' \subseteq C$ be the x - y path in C , then $e(P) < e(P')$. This means that P and P' are distinct paths and so there is some $q \in V(P') - V(P)$.

Since P and P' are both x - y walks, $|P \cap P'| \geq 2$. Therefore, there are $p_1, p_2 \in P \cap P'$ which are connected to q , which implies that there is a p_1 - p_2 path in P' . Since p_1 and p_2 are connected in P , we have found 2 different p_1 - p_2 paths and so there is some cycle $Q \subseteq P \cup P'$. Therefore,

$$\begin{aligned} e(Q) &\leq e(P \cup P') \\ &\leq e(P) + e(P') \\ &\leq \text{diam}(G) + d_C(x, y) \\ &\leq 2d_C(x, y) - 1 \\ &= 2 \left\lfloor \frac{e(C)}{2} \right\rfloor - 1 \\ &< e(C), \end{aligned}$$

which is a contradiction. □

For readers with knowledge in real analysis or topology, it is easy to see that an undirected unweighted connected graph is a metric space with distance between vertices as its metric.

Theorem 1.2.16 ▶ Connected Graph as A Metric Space

If G is connected, then $(V(G), d_G)$ is a metric space.

Proof. Clearly, for all $x, y \in V(G)$, $d_G(x, y) \geq 0 \in V(G)$ with $d_G(x, y) = 0$ if and only if $x = y$ and $d_G(x, y) = d_G(y, x)$.

Let U, V be the shortest u - w path and shortest w - v path respectively, then $U + V$ is a u - v walk with length $d(u, w) + d(w, v)$. Since the shortest u - v path has length $d(u, v)$, we have

$$d(u, v) \leq d(u, w) + d(w, v).$$

Therefore, $(V(G), d_G)$ is a metric space. □

An application of Theorem 1.2.16 allows us to establish the following:

Theorem 1.2.17 ► Boundedness of Diameter

If G is connected, then

$$\text{rad}(G) \leq \text{diam}(G) \leq 2\text{rad}(G).$$

Proof. $\text{rad}(G) \leq \text{diam}(G)$ is immediate from Definition 1.2.14. Take $u, v \in V(G)$ with $d(u, v) = \text{diam}(G)$ and take $w \in V(G)$ such that $e(w) = \text{rad}(G)$. Notice that this implies

$$d(u, w) \leq e(w) = \text{rad}(G)$$

$$d(w, v) \leq e(w) = \text{rad}(G).$$

By Theorem ??,

$$\text{diam}(G) = d(u, v) \leq d(u, w) + d(w, v) = 2\text{rad}(G).$$

□

1.3 Graphs and Matrices

So far we have been using hand-drawn illustrations to aid us in graph visualisation. However, for large graphs with many vertices and edges, drawing out the graph structures becomes nearly impossible. Therefore, we need to use some algebraic tools to help us represent a large graph.

Definition 1.3.1 ► Adjacency Matrix

Let G be a multigraph with $v(G) = n$, then the **adjacency matrix** denoted by $\mathbf{A}(G)$ is an $n \times n$ matrix such that a_{ij} is the number of edges incident to both $v_i, v_j \in V(G)$.

Remark. For an undirected multigraph, \mathbf{A} is always symmetric.

Note that an adjacency matrix does not tell us which edges are incident to a particular vertex, so we may consider the following alternative:

Definition 1.3.2 ▶ Incidence Matrix

Let G be a multigraph with $v(G) = n$ and $e(G) = m$, then the **incidence matrix** denoted by $\mathbf{M}(G)$ is an $n \times m$ matrix such that

$$m_{ij} = \begin{cases} 1, & \text{if } e_j \text{ is incident with } v_i \\ 0, & \text{otherwise} \end{cases}.$$

Remark. For an undirected multigraph, consider an arbitrary k -th column of \mathbf{M} . Note that any column will have exactly 2 non-zero entries. Suppose $m_{ik} = m_{jk} = 1$, it means that $e_k = v_i v_j$.

For readers who have learnt about basic data structures in computer science, an incidence matrix is just an adjacency list with each list of neighbours converted to a (non-compact) boolean array.

Note that the sum of the i -th row for both \mathbf{A} and \mathbf{M} is the degree of vertex i .

Since \mathbf{A} and \mathbf{M} carries information about adjacencies between vertices, we can use them to draw some conclusions regarding graph traversal.

Proposition 1.3.3 ▶ Counting the Number of Walks between Two Vertices

Let G be a simple graph of order n with adjacency matrix \mathbf{A} , then the (i, j) entry of \mathbf{A}^k is the number of v_i - v_j walks of length k .

Proof. The case where $k = 1$ is trivially true since there is a v_i - v_j walk of length 1 if and only if v_i and v_j are neighbours.

Let the (i, j) entry of \mathbf{A}^m be m_{ij} . Suppose m_{ij} is the number of v_i - v_j walks of length m . Then the (i, j) entry of \mathbf{A}^{m+1} is given by

$$\sum_{r=1}^n m_{ir} a_{rj}.$$

Notice that m_{ir} is the number of v_i - v_r walks of length m and a_{rj} is the number of v_r - v_j walks of length 1, so by Theorem ??, $m_{ir} a_{rj}$ is the number of v_i - v_j walks of length n that passes through v_r . Therefore, summing up $m_{ir} a_{rj}$ for $r = 1, 2, \dots, n$ gives the total number of v_i - v_j walks of length $n + 1$. \square

Additionally, we have the following corollary:

Corollary 1.3.4 ▶ Connectedness Test

Let G be a graph with $v(G) \geq 2$ and adjacency matrix A . Let

$$B = \sum_{i=1}^{n-1} A^i,$$

then G is connected if and only if $b_{ij} \neq 0$ for all $i \neq j$.

As it turns out, the incidence and adjacency matrices are related by a simple equation.

Proposition 1.3.5

Let M and A be the incidence matrix and adjacency matrix of a simple graph G respectively, then

$$MM^T = \begin{bmatrix} d_1 & 0 & 0 & \cdots & 0 \\ 0 & d_2 & 0 & \cdots & 0 \\ 0 & 0 & d_3 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & d_n \end{bmatrix} + A.$$

1.4 Tree

In computer science and data science, it is often useful to use a tree diagram. Colloquially, we view a tree as a graph consisting of nodes, each of which has exactly one parent node and some children nodes. Here, we shall introduce the rigorous mathematical definition for a tree.

Definition 1.4.1 ▶ Tree and Forest

A **forest** is an acyclic graph. A **tree** is a connected forest.

In other words, a tree is an **connected acyclic graph**. We also have the following alternative definition for a tree:

Theorem 1.4.2 ▶ Equivalent Definitions of a Tree

The followings are equivalent:

1. T is a tree.
2. For any $u, v \in V(T)$, there exists a unique u - v path in T .

3. T is minimally connected, i.e., T is connected but $T - e$ is disconnected for any $e \in E(T)$.
4. T is maximally acyclic, i.e., T is acyclic but $T + xy$ for any $x, y \in V(T)$ with $xy \notin E(T)$ is cyclic.

Proof. Let T be a tree. For any $u, v \in V(T)$, there exists a u - v path $P \subseteq T$. Suppose $P' \subseteq T$ is also a u - v path, then there exists a non-trivial closed walk between u and v which contains a cycle, leading to a contradiction.

Suppose T is such that any $u, v \in V(T)$ are connected by a unique path. Suppose on contrary $T - e$ is connected for some $e = xy \in E(T)$, then there exists some x - y path in T which does not contain xy . However, xy is a different x - y path, which is a contradiction.

Suppose T is minimally connected. Note that if T contains some cycle C , then for any $e \in E(C)$, $T - e$ is connected. So T being minimally connected implies that T is acyclic. Take any $x, y \in V(T)$ with $xy \notin E(T)$, then there exists some x - y path $P \subseteq T$ which does not contain xy . Therefore, $P + xy$ is a cycle, which implies that T is maximally acyclic.

Suppose T is maximally acyclic. Suppose T is not connected, then there exists $u, v \in V(T)$ which are disconnected. Note that $T + uv$ is acyclic because uv is the unique u - v path. Therefore, T is not maximally acyclic. The contrapositive shows that T being maximally acyclic implies that T is a tree. \square

We first consider the following proposition:

Proposition 1.4.3 ► Degrees of Vertices in a Tree

Let T be a tree with $\Delta(T) = k$. Let n_i be the number of vertices in T of degree i , then

$$n_1 = 2 + \sum_{i=1}^{k-2} i n_{i+2}.$$

Proof. Let the order of T be n , then $n = \sum_{i=1}^k n_i$. By Lemma 1.1.7, we have

$$\sum_{v \in V(T)} d(v) = 2(n - 1).$$

However, since there are n_i vertices with degree i , we have

$$\sum_{v \in V(T)} d(v) = \sum_{i=1}^k i n_i.$$

Therefore,

$$\begin{aligned} 2 \sum_{i=1}^k n_i - 2 &= \sum_{i=1}^k i n_i \\ n_1 &= \sum_{i=3}^k i n_i \\ n_1 &= \sum_{i=1}^{k-2} i n_{i+2}. \end{aligned}$$

□

The following corollary is an immediate consequence of Proposition 1.4.3:

Corollary 1.4.4 ► Number of End Vertices in a Tree

A tree of order at least 2 contains at least 2 end vertices.

In particular, a tree with exactly 2 end vertices is a doubly linked list. We will now give a name to these vertices in a tree whose degree is 1.

Definition 1.4.5 ► Leaf

Let G be a tree. A **leaf** of G is a vertex $v \in V(G)$ with $d_G(v) = 1$.

Given any tree, we can fix a vertex as the “root”. We can carry out depth-first search to traverse the tree’s vertices starting from the root. An interesting phenomenon here is that at any point of time, we notice that the vertex which we are currently at is adjacent to exactly one of the vertices which we have visited.

Proposition 1.4.6 ► Re-labelling of Vertices in a Tree

Let T be a tree with order n , then there exists an ordering of $V(T)$ such that for any $v_k \in V(T)$, v_k is adjacent to exactly one of v_1, v_2, \dots, v_{k-1} .

Proof. By Corollary 1.4.4, T has a leaf vertex. Let this vertex be v_n . Note that $T - v_n \subseteq T$, so it is acyclic. Let $T' = T - v_n$, then v_n has a unique neighbour in $V(T')$. Note that T' is also a tree, so we can repeat this process to take v_{n-1} . Continue doing so

until we have taken all vertices in T , then for any $k = 1, 2, \dots, n$, v_k has a unique neighbour in v_1, v_2, \dots, v_k . \square

In fact, such an ordering of the tree is known as a *topological sort*.

Intuitively, if a connected graph contains cycles, we can always reduce it to a tree by deleting some edges. This leads to the following result:

Corollary 1.4.7 ► Number of Edges in a Tree

A connected graph T is a tree of order n if and only if $e(T) = n - 1$.

Proof. If T is a tree, then by Proposition 1.4.6 we can order $V(T)$ such that for all $i = 2, 3, \dots, n$, v_i is adjacent to exactly one vertex from v_1, v_2, \dots, v_{i-1} . Therefore, $e(T) = n - 1$.

If $e(T) = n - 1$, note that T contains a tree $T' \subseteq T$ which has n vertices. Therefore, $e(T') = n - 1 = e(T)$. This implies that $T = T'$, so T is a tree. \square

Recall that every graph contains a tree. In fact, this result can be further strengthened.

Proposition 1.4.8 ► Existence of Subgraph Trees

Let T be a tree with k vertices. If G is a graph with $\delta(G) \geq k - 1$, then G contains a subgraph which is isomorphic to T .

Proof. Fix an ordering on $V(T)$ such that v_i has a unique neighbour in v_1, v_2, \dots, v_{i-1} . Take any vertex in G to be v_1 . Suppose we have chosen v_1, v_2, \dots, v_i in G for some $i < k$, for any v_j among these vertices, at most $(i - 1)$ of v_j 's neighbours have been chosen, but

$$d_G(v_j) \geq \delta(G) = k - 1 > i - 1.$$

Therefore, there exists some $u \in N_G(v_j)$ which is not one of v_1, v_2, \dots, v_i . Take u as v_{i+1} with the edge uv_j , then v_{i+1} is adjacent to exactly one of v_1, v_2, \dots, v_i . This means we can choose all vertices of T from $V(G)$, which means $T \subseteq G$. \square

1.5 Bipartite Graphs

Consider a tree T . Take some $r \in V(T)$ as the root. We define a vertex $v \in V(T)$ to be at depth k from the root if there is a r - v path of length k . Clearly, if we partition $V(T)$ into vertices of odd depth and even depth, we can easily see that all edges in T joins one vertex from the former to one from the latter.

In fact, there are many graphs which can be bi-partitioned in a similar manner, which are known as *bipartite* graphs.

Definition 1.5.1 ► Bipartite Graph

A graph G is **bipartite** if $V(G)$ can be partitioned into two disjoint subsets V_1 and V_2 such that every edge of G joins a vertex in V_1 to a vertex in V_2 . (V_1, V_2) is known as a **bipartition** of G .

Note that the size of a bipartite graph G with partite sets V_1 and V_2 is just

$$e(G) = \sum_{x \in V_1} d_G(x) = \sum_{y \in V_2} d_G(y).$$

It can be deduced that the maximal size of a bipartite graph is achieved when every vertex in V_1 is connected to every vertex in V_2 . To define this rigorously, we first introduce the notion of *join*.

Definition 1.5.2 ► Join

Let G_1 and G_2 be two disjoint graphs of order n_1 and n_2 respectively. The **join** of G_1 and G_2 , denoted by $G_1 + G_2$ is the graph such that

$$\begin{aligned} V(G_1 + G_2) &= V(G_1) \cup V(G_2) \\ E(G_1 + G_2) &= E(G_1) \cup E(G_2) \cup \{uv : u \in V(G_1), v \in V(G_2)\}. \end{aligned}$$

Informally, we can describe the join of G_1 and G_2 as a graph which contains all the vertices from G_1 and G_2 , all existing edges from G_1 and G_2 , and new edges connecting every vertex in G_1 to every vertex in G_2 . Thus, we can define a complete bipartite graph using a join.

Definition 1.5.3 ► Complete Bipartite Graph

A **complete bipartite graph** is defined as $K_{p,q} = 0_p + 0_q$.

Consider a k -regular bipartite graph. Intuitively, if every vertex in the first partite set must be adjacent to $k > 0$ vertices in the second partite set and vice versa, then it is only natural that the two partite sets have equal cardinalities.

Proposition 1.5.4 ► Regular Bipartite Graph

For all $k \in \mathbb{Z}^+$, a k -regular bipartite graph with bipartition (U, V) is such that $|U| = |V|$.

Proof. Note that we have

$$k|U| = e(G) = k|V|.$$

Since $k > 0$, this implies $|U| = |V|$. □

It is not easy to see whether a graph is bipartite by observation alone, so we consider the following characterisation:

Theorem 1.5.5 ► Bipartite Graph Characterisation

A graph is bipartite if and only if it contains no odd cycles.

Proof. The necessity following from the previous argument, so we only prove the sufficiency. Suppose G contains no odd cycles. Note that there exists some spanning tree $T \subseteq G$ with root u . For every $v \in V(T)$, v is coloured red if $d_T(u, v)$ is odd, and blue otherwise.

Suppose that there exist some $w_1, w_2 \in V(G)$ such that both receive the same colour but $w_1 w_2 \in E(G)$. Note that this means that there exist a w_1 - u path in T and a w_2 - u path in T with the same parity. This implies that there exists an closed walk of odd length in G , and so G contains an odd cycle, which is a contradiction. Therefore, G is bi-colourable and so is bipartite. □

Matchings and Vertex Covers

2.1 Matching

In set theory, we define the notion of a function

$$f : X \rightarrow Y$$

as a mapping such that every $x \in X$ has a unique image in Y . In a graph-theoretical perspective, we can view X and Y as vertex sets and a “mapping” in this case can be seen as a set of disjoint edges joining a vertex from X to a vertex from Y .

Definition 2.1.1 ► Matching

A **matching** in a graph G is a set $M \subseteq E(G)$ of vertex-disjoint edges.

The term “vertex-disjoint edges” means that for any $e, f \in M$, they are not incident to the same vertex in G . Here we define two notions which sound similar:

Definition 2.1.2 ► Maximal and Maximum Matchings

A **maximal matching** is a matching $M \subseteq E(G)$ such that for all $e \in E(G) - M$, $M \cup \{e\}$ is not a matching.

A **maximum matching** is a matching $M \subseteq E(G)$ such that for any matching $N \subseteq E(G)$, $|N| \leq |M|$.

It is clear that a maximum matching must be maximal but not the other way round.

Definition 2.1.3 ► Matching Number

The **matching number** of a graph G is the size of the maximum matching in G , denoted as $\nu(G)$.

Clearly, for any graph G , $\nu(G) \leq \frac{v(G)}{2}$ as the best we can do is to partition $V(G)$ into disjoint pairs of vertices with respect to $E(G)$.

Definition 2.1.4 ▶ Perfect Matching

Let G be a graph. We say that G has a **perfect matching** if $\nu(G) = \frac{v(G)}{2}$.

Remark. In particular, if G is a bipartite graph with partite sets A and B , we say that a matching $M \subseteq G$ is perfect to A if for any $a \in A$, $a \in M$.

Intuitively, if G has a perfect matching, then we can find a bipartition (U, V) of $V(G)$ such that there exists a bijection between U and V .

Definition 2.1.5 ▶ Vertex Covering Number

Let G be a graph. A **vertex cover** of G is defined to be a set $S \subseteq V(G)$ such that for all $e \in E(G)$, there is some $v \in S$ such that $v \in e$. The **vertex covering number** is defined as the size of the smallest vertex cover of G , denoted as $\tau(G)$.

Now let us examine some special graphs:

- Complete graph K_n : $\nu(K_n) = \left\lfloor \frac{n}{2} \right\rfloor$, $\tau(K_n) = n - 1$.
- Cycle C_n : $\nu(C_n) = \left\lfloor \frac{n}{2} \right\rfloor$, $\tau(C_n) = \left\lceil \frac{n}{2} \right\rceil$.
- Path P_n : $\nu(P_n) = \left\lfloor \frac{n+1}{2} \right\rfloor$, $\tau(P_n) = \left\lceil \frac{n}{2} \right\rceil$.
- Complete bipartite graph $K_{m,n}$: $\nu(K_{m,n}) = \tau(K_{m,n}) = \min\{m, n\}$.
- Hypercube graph Q^d : $\nu(Q^d) = \tau(Q^d) = 2^{d-1}$.
- Petersen graph P : $\nu(P) = 5$, $\tau(P) = 6$.

We may have guessed based on the above observation that $\tau(G) \geq \nu(G)$ for all graphs.

Proposition 2.1.6 ▶ Vertex Covering Number Is at Least Matching Number

For any graph G , $\tau(G) \geq \nu(G)$.

Proof. Fix $M := \{e_1, e_2, \dots, e_{\nu(G)}\}$ to be a maximum matching in G . Let $S \subseteq V(G)$ be any vertex cover of G . For any $i = 1, 2, \dots, \nu(G)$, we have $|e_i \cap S| \geq 1$, otherwise S does not cover e_i . Therefore,

$$\tau(G) = |S| = \sum_{i=1}^{\nu(G)} |e_i \cap S| \geq \nu(G).$$

□

2.2 Clique and Independent Set

Given any graph G , then theoretically, if we were to find a subgraph of order n , the one with the greatest size is a complete graph and that with the smallest size is an empty graph.

Definition 2.2.1 ► Clique

A **clique** in G is a complete subgraph of G . The **clique number** of G is the order of the largest clique in G , denoted as $\omega(G)$.

Definition 2.2.2 ► Independent Set

The **independent set** of G is a subset $I \subseteq V(G)$ such that for all $u, v \in I$, $uv \notin E(G)$. The **independence number** of G , denoted as $\alpha(G)$, is the size of the largest independent set in G .

Intuitively, if a set $S \subseteq V(G)$ induces an empty subgraph in G , it will induce a complete subgraph in \bar{G} . Therefore, $\alpha(G) = \omega(\bar{G})$.

We shall examine the independence numbers of some special graphs.

- Complete graph K_n : $\alpha(K_n) = 1$.
- Cycle C_n : $\alpha(C_n) = \left\lfloor \frac{n}{2} \right\rfloor$.
- Path P_n : $\alpha(P_n) = \left\lfloor \frac{n+1}{2} \right\rfloor$.
- Complete bipartite graph $K_{m,n}$: $\alpha(K_{m,n}) = \max\{m, n\}$.
- Hypercube graph Q^d : $\alpha(Q^d) = 2^{d-1}$.
- Petersen graph P : $\alpha(P) = 4$.

The following theorem discusses the numerical relationship between the independence number of vertex covering number:

Proposition 2.2.3 ► Sum of Independent Number and Vertex Covering Number

For any graph G of order n , $\alpha(G) + \tau(G) = n$.

Proof. It suffices to prove that S is an independent set in G if and only if $V(G) - S$ is a vertex cover of G .

Let $S \subseteq V(G)$ be an independent set, then for any edge $e = uv \in E(G)$, at least one of u and v is in $V(G) - S$ for otherwise there exists $u, v \in S$ such that $u \sim v$, which is not possible. Therefore, $V(G) - S$ is a vertex cover.

Suppose conversely that $S \subseteq V(G)$ is such that $V(G) - S$ is a vertex cover. □

So far we have been talking a lot about the Petersen graph, but it turns out that the Petersen graph can be generalised into a *Kneser graph*.

Definition 2.2.4 ► Kneser Graph

The **Kneser graph** is a graph $KG(n, k)$ such that

$$\begin{aligned} V(KG(n, k)) &= \{S \in \mathcal{P}([n]) : |S| = k\}, \\ E(KG(n, k)) &= \{(S, T) : S \cap T = \emptyset\}. \end{aligned}$$

The vertex set of a Kneser graph is the set of all k -element subsets of $\{1, 2, \dots, n\}$ and two vertices are adjacent if and only if their corresponding subsets are disjoint.

We introduce a theorem closely related to the Kneser graph:

Theorem 2.2.5 ► Erdos-Ko-Rado Theorem

Let $n \geq 2k$, then any family

$$\mathcal{F} \subseteq \{S \in \mathcal{P}([n]) : |S| = k\}$$

with $S \cap T \neq \emptyset$ for all $S, T \in \mathcal{F}$ is such that $|\mathcal{F}| \leq \binom{n-1}{k-1}$.

We can see that \mathcal{F} is in fact a subset of $V(KG(n, k))$, so this is equivalent to saying that the biggest subset of $V(KG(n, k))$ such that no vertices are adjacent is C_{k-1}^{n-1} , which is just to prove that $\alpha(KG(n, k)) = C_{k-1}^{n-1}$.

Another property of the independence number is related to the notion of a *line graph*.

Definition 2.2.6 ► Line Graph

Let G be a graph. The **line graph** of G is defined as $L(G)$ with $V(L(G)) = E(G)$ and

$$E(L(G)) := \{(e, f) \in E(G)^2 : e \neq f, e \cap f \neq \emptyset\}.$$

In other words, $L(G)$ uses $E(G)$ as the vertex set and two vertices are adjacent if and only if the respective edges share at least 1 common vertex in G .

Proposition 2.2.7 ▶ Independence Number of Line Graphs

For any graph G , $\nu(G) = \alpha(L(G))$.

Proof. Fix a maximum matching $M \subseteq G$, then for every $e, f \in E(M)$ with $e \neq f$, we have $ef \notin E(L(G))$, therefore, $E(M)$ is an independent set in $L(G)$ and so $\alpha(L(G)) \geq \nu(G)$.

Suppose $\alpha(L(G)) > \nu(G)$, then there exists some $e_0 \in V(L(G)) = E(G)$ such that e_0 is vertex-disjoint with all $e \in E(M)$. However, this means that we can find a matching with bigger size in G , which is a contradiction. Therefore,

$$\nu(G) = \alpha(L(G)).$$

□

2.3 Matchings in Bipartite Graphs

Let us take a slight detour and unpack the matching number from a different perspective. Note that while forming a matching in a graph G , we actually divide $E(G)$ into two subsets, one of which is included in the matching and the other excluded. Now, let us denote an included edge by letting it have a weight of 1, and assign 0 weight to all other edges which are unselected.

For every $e \in E(G)$, let x_e denote its weight. This way, to find a maximum matching is in fact equivalent to finding an optimal solution for the *integer program*

$$\begin{aligned} & \max \sum_{e \in E(G)} x_e \\ & \text{such that } x_e \in \{0, 1\}, \\ & \sum_{v \in e} x_e \leq 1 \quad \text{for all } v \in V(G), \end{aligned}$$

where the optimal value is just $\nu(G)$. Similarly, we can assign 0-1 weights, y_v , to every $v \in V(G)$, then a vertex cover is equivalent to an optimal solution for the integer program

$$\begin{aligned} & \min \sum_{v \in V(G)} y_v \\ & \text{such that } y_v \in \{0, 1\}, \\ & \sum_{v \in e} y_v \geq 1 \quad \text{for all } e \in E(G), \end{aligned}$$

where the optimal value is just $\tau(G)$. We can relax both programs into linear programs and it is clear that the 2 programs form a pair of primal and dual problems. Let the optimal values for the 2 linear programs be $\nu^*(G)$ and $\tau^*(G)$ respectively. By considering strong duality of linear programs, we can check that

$$\nu(G) \leq \nu^*(G) = \tau^*(G) \leq \tau(G).$$

Here $\nu^*(G)$ and $\tau^*(G)$ are known as *fractional matching number* and *fractional vertex covering number* respectively.

It turns out that for bipartite graphs, the above inequality can be further strengthened to strict equality. We shall first discuss a few useful concepts.

Fix some matching M in a bipartite graph G . Intuitively, we can find some paths in G which consisting of alternating edges from M and $G - M$.

Definition 2.3.1 ► Alternating Path

Let G be a graph and fix $M \subseteq G$ to be a matching. An **alternating path** in G with respect to M is a path $v_1v_2 \cdots v_n$ such that $v_1v_2 \in G - M$, $v_kv_{k+1} \in M$ for all even k and $v_kv_{k+1} \in G - M$ for all odd k .

Intuitively, if an alternating path contains more edges from $G - M$ than from M , we can utilise it to extend the matching M by doing a switch of edges.

Definition 2.3.2 ► Augmenting Path

An **augmenting path** with respect to a matching M in G is an alternating path which ends at some $v \in V(G) - V(M)$

In general, we can characterise a maximum matching by using augmenting paths.

Theorem 2.3.3 ► Maximum Matching Characterisation

A matching $M \subseteq G$ is maximum if and only if there is no augmenting path in G with respect to M .

Proof. Suppose M is a maximum matching in G . We will prove that there is no augmenting path in G with respect to M by considering the contrapositive statement. Suppose we can find some augmenting path $P := v_1v_2 \cdots v_n$ in G with respect to M , then P must contain an odd number of edges. Consider the subgraph

$$M' := M - \{v_iv_{i+1} \in P : i \text{ is even} \} + \{v_jv_{j+1} \in P : j \text{ is odd} \}.$$

Note that M' is clearly a matching and $e(M') = e(M) + 1$, so M is not a maximum matching.

Suppose conversely that there is no augmenting path in G with respect to M . We will prove that M is maximum by considering the contrapositive statement. Suppose that M is not maximum, then there exists some matching M' with $e(M') > e(M)$. Consider the subgraph $H := M \triangle M'$. Note that $\Delta(H) = 2$ and that every connected component of H is either a path or a cycle whose edges alternate between $E(M)$ and $E(M')$. Note that H is bipartite, so every cycle in H must be even and so contain equal number of edges from M and M' . However, since $e(M') > e(M)$, we can find a path in H which begins and ends with edges in $M' - M$ and whose edges alternate between M and M' . This path is an augmenting path with respect to M . \square

With these preliminary results established, we are now ready to prove *König's Theorem*.

Theorem 2.3.4 ► König's Theorem

If G is bipartite, then $\nu(G) = \tau(G)$.

Proof. By Proposition 2.1.6, we already know that $\nu(G) \leq \tau(G)$. Therefore, it suffices to prove that $\nu(G) \geq \tau(G)$. Fix $M \subseteq G$ to be a maximum matching. Let (A, B) be a bipartition of G , then for every $e \in E(M)$, we have $e = v_A v_B$ for some $v_A \in A$ and $v_B \in B$.

We select a subset of vertices from $V(M)$ with the following algorithm: for each $v_A v_B \in E(M)$, we take v_B if there exists some alternating path starting at a vertex in A ends at v_B . Otherwise, we take v_A . Let the vertex set produced this way be U . We claim that U is a vertex cover for G .

Take any edge $ab \in E(G)$. If $ab \in E(M)$, then $a \in U$ or $b \in U$. Otherwise, since M is a maximum matching in G which is bipartite, at least one of a and b is matched.

If $b \in V(M)$, consider a . If $a \notin V(M)$, then ab is an alternating path and so $b \in U$. Otherwise, $a \in V(M)$ which reduces the case to the other case.

If $a \in V(M)$ and $a \in U$ then we are done. Otherwise, $a \notin U$. Suppose $ab' \in E(M)$, then $b' \in U$. This means that we can find some alternating path P with respect to M which ends at b' . If $b \in P$, then there is some alternating path with

respect to M which ends at b . Otherwise, note that $a \notin P$ because a is matched, so $P + ab$ is an alternating path which ends at b with respect to M . Since M is maximum, by Theorem 2.3.3, this alternating path is not augmenting, which means that $b \in V(M)$. Therefore, $b \in U$.

Therefore, U is a vertex cover for G . Note that $|U| = \nu(G)$, so $\tau(G) \leq \nu(G)$. This means that $\nu(G) = \tau(G)$. \square

We can generalise Theorem 2.3.4 to *fractional vertex covers*.

Definition 2.3.5 ▶ Fractional Vertex Cover

The **fractional vertex cover** of a non-negatively weighted graph G is defined as the function

$$c: V(G) \rightarrow \mathbb{R}_0^+$$

such that $c(v) + c(u) \geq w(uv)$ for all $u, v \in V(G)$, where $w: E(G) \rightarrow \mathbb{R}_0^+$ is the weight function.

We shall state the generalised theorem without proof.

Theorem 2.3.6 ▶ Egerváry's Theorem

For every bipartite G , the minimum weight of a fractional vertex cover equals the weight of the matching with the maximum weight.

Suppose G is a bipartite graph with bipartition (A, B) . In the case where $|A| \neq |B|$ we cannot get any matching with size greater than $\min\{|A|, |B|\}$ for the obvious reason. Therefore, the best we can hope is to construct a matching **perfect to one of the partite sets**.

Suppose $S \subseteq A$ is a set of vertices in G . We denote the union of the neighbourhoods of all vertices in S by $N_G(S)$. Apparently, if we can find some S such that $|N_G(S)| < |S|$, it means that we cannot find a matching perfect to A because we cannot match every vertex in S .

This means that for G to contain a matching perfect to A , it necessarily needs to satisfy $|S| \leq |N_G(S)|$ for every $S \subseteq A$. However, it turns out that amazingly, this necessary condition alone is also sufficient to ascertain the existence of a matching perfect to A .

Theorem 2.3.7 ▶ Hall's Theorem

Let G be a bipartite graph G with bipartition (A, B) . G contains a matching perfect to A if and only if for every $S \subseteq A$,

$$|N_G(S)| \geq |S|.$$

Proof. Suppose $M \subseteq G$ is a matching perfect to A . Let $S \subseteq A$ be any subset. Clearly, for each $a \in S$, there exists a unique $b \in B$ such that $ab \in E(M)$ and if $ab, a'b' \in E(M)$ for $a \neq a'$, we have $b \neq b'$. Therefore, $|N_G(S)| \geq |S|$.

Suppose that for every $S \subseteq A$, $|N_G(S)| \geq |S|$, we take any matching $M \subseteq G$ such that $A - V(M) \neq \emptyset$. Take (a_0, b_1, a_1, \dots) to be a finite sequence of pair-wise distinct vertices with greatest length such that a_0 is unmatched, b_i is adjacent to some $a_{f(i)} \in \{a_0, a_1, \dots, a_{i-1}\}$ in G and $b_i a_i \in M$ for all $i \geq 1$.

We claim that this sequence does not end in A . Suppose on contrary that the sequence ends at some $a_{n-1} \in A$. Take $T = \{a_0, a_1, \dots, a_{n-1}\}$, then $|N_G(T)| \geq n$. Therefore, there exists some $b_n \in N_G(T) - \{b_1, b_2, \dots, b_{n-1}\}$, which is a contradiction because we can now extend the length of the sequence.

Let b_k be the end of the sequence, then the path $P := a_0 b_1 a_{f(1)} b_2 a_{f(2)} \dots a_{f(k-1)} b_k$ is an alternating path. If b_k is matched to some $a \in A \cap V(M)$, we know that $a \notin \{a_1, a_2, \dots, a_{k-1}\}$ because that would imply $b_k = b_i$ for some $i \in \{1, 2, \dots, k-1\}$, which is a contradiction. Since a_0 is unmatched, we have find a longer sequence satisfying our construction, which is not possible. Therefore, b_k must be unmatched. This means that P is an augmenting path and so by Theorem 2.3.3 M is not a maximum matching. This means that the maximum matching in G must be perfect to A . \square

Beside the above proof, there are several alternative ways to prove Theorem 2.3.7. Here we first present a proof by contradiction using Theorem 2.3.4.

Proof for Hall's Theorem by König's Theorem

Proof. Observe that it suffices to show that $\nu(G) = |A|$. First, note that since G is bipartite, it is not possible to have $\nu(G) > |A|$ because otherwise there exists an edge between 2 distinct vertices in B . Suppose on contrary that $\nu(G) < |A|$, then by Theorem 2.3.4, $\tau(G) = \nu(G) < |A|$. This means that there exists a vertex cover with strictly less vertices than A .

Suppose $U = A' \cup B'$ is a vertex cover for G with $A' \subseteq A$ and $B' \subseteq B$, then $|A'| + |B'| < |A|$. Clearly, there is no edge between $A - A'$ and $B - B'$. Take $S := A - A'$, then $N_G(S) \subseteq B'$. Therefore,

$$|N_G(S)| \leq |B'| < |A| - |A'| = |S|,$$

which is a contradiction. □

Another proof uses an argument by strong induction:

Proof for Hall's Theorem by Strong Induction

Proof. We shall perform strong induction on $|A|$. The case where $|A| = 1$ is trivial. Suppose that for all $|A| < n$, the theorem holds. Let G be a bipartite graph with bipartition (A, B) such that $|A| = n$. We consider 2 cases.

Suppose that for any proper subset $S \subset A$, we have $|N_G(S)| \geq |S| + 1$. Consider an edge $ab \in E(G)$ and define $G' := G - \{a, b\}$ be the graph with the vertices a and b removed. Let (A', B') be the bipartition of G' . Notice that for any $S' \subseteq A'$, we have $|N_{G'}(S')| \geq |S'|$. By the inductive hypothesis, this means that G' contains a matching M' perfect to A' . Clearly, $M' + ab$ is a matching perfect to A in G .

Suppose otherwise that there exists some proper subset $A' \subset A$ with $|N_G(A')| = |A'|$. Let $B' := N_G(A')$ and define

$$G' := G[A' \cup B'], \quad G'' := G[(A - A') \cup (B - B')].$$

Note that for any $S \subseteq A'$, $N_G(S) \subseteq B'$, and so $|N_{G'}(S)| = |N_G(S)| \geq |S|$. By the inductive hypothesis, this implies that G' contains a matching M' perfect to A' . For any $T \subseteq A - A'$, we claim that $|N_{G''}(T)| \geq |T|$.

Suppose on contrary that $|N_{G''}(T)| < |T|$. Note that $N_G(T \cup A') \subseteq N_{G''}(T) \cup B'$, so

$$|N_G(T \cup A')| \leq |N_{G''}(T)| + |B'| < |T| + |A'| = |T \cup A|,$$

which is a contradiction. Therefore, this implies that G'' contains a matching M'' perfect to $A - A'$. Note that $M' \cup M''$ is a matching in G perfect to A . □

The last proof we are going to present stems from the following observation: suppose we have a graph G satisfying the conditions in Hall's Theorem, we wish to delete "redundant" edges until we cannot remove any more edge without violating the condition. We claim that the remaining graph is a matching perfect to A .

Proof for Hall's Theorem by Edge-Minimal Subgraph

Proof. Let $H \subseteq G$ be the subgraph with the smallest size such that for every $S \subseteq A$, $|N_H(S)| \geq |S|$. We shall prove that H is a matching perfect to A .

First, observe that $d_H(a) \geq 1$ for all $a \in A$. Suppose on contrary that H is not a matching perfect to A , then there exists some $a \in A$ which has two distinct neighbours $b_1, b_2 \in B$ in H . Define $H_1 := H - ab_1$ and $H_2 := H - ab_2$, then by the minimality of H , there exist subsets $A_1, A_2 \subseteq A$ both containing a such that $|N_{H_1}(A_1)| < |A_1|$ and $|N_{H_2}(A_2)| < |A_2|$. By our construction of H_1 and H_2 , we know that $b_1 \in N_{H_2}(A_2) - N_{H_1}(A_1)$ and $b_2 \in N_{H_1}(A_1) - N_{H_2}(A_2)$. Consider

$$S := A_1 \cap A_2 - \{a\},$$

then $N_H(S) \subseteq N_{H_1}(A_1) \cap N_{H_2}(A_2)$. Therefore,

$$\begin{aligned} |N_H(S)| &\leq |N_{H_1}(A_1) \cap N_{H_2}(A_2)| \\ &= |N_{H_1}(A_1)| + |N_{H_2}(A_2)| - |N_{H_1}(A_1) \cup N_{H_2}(A_2)| \\ &= |N_{H_1}(A_1)| + |N_{H_2}(A_2)| - |N_H(A_1 \cup A_2)| \\ &\leq |A_1| - 1 + |A_2| - 1 - |N_H(A_1 \cup A_2)| \\ &= |A_1 \cap A_2 - \{a\}| - 1, \end{aligned}$$

which is a contradiction. □

Here we introduce a famous corollary of Hall's Theorem:

Corollary 2.3.8 ► Regular Bipartite Graphs Have A Perfect Matching

If G is a d -regular bipartite graph with bipartition (A, B) , then G has a perfect matching.

Proof. It suffices to prove that G contains a matching perfect to A . Since $e(G) = d|A| = d|B|$, we have $|A| = |B|$. Take any $X \subseteq A$ and consider the induced subgraph

$$H := G[X \cup N_G(X)].$$

Note that for every $v \in N_G(X)$, $d_H(v) \leq d_G(v) = d$, so $d|N_G(X)| \geq e(H) = d|X|$. Therefore, $|X| \leq |N_G(X)|$ and by Theorem 2.3.7, G contains a matching perfect to A . □

The above result immediately leads to the following corollary:

Corollary 2.3.9 ► Decomposition of Regular Bipartite Graphs

Let G be a d -regular bipartite graph, then $E(G)$ can be decomposed into perfect matchings.

Proof. By Corollary 2.3.8, we can find some perfect matching M_d in G . Consider the graph G' with $V(G') = V(G)$ and $E(G') = E(G) - E(M_d)$, then G' is a $(d-1)$ -regular bipartite graph and so it contains a perfect matching M_{d-1} . Note that $E(M_{d-1}) \cap E(M_d) = \emptyset$ and that M_{d-1} is also a perfect matching in G . Repeat this process until we have used all edges in G . The set of all perfect matchings obtained this way forms a partition of $E(G)$. \square

Can we derive a similar result for any kind of graphs in general? It turns out that this curious question is closely related to the number of connected components with odd orders in a graph. We denote this quantity by $o(G)$ for any graph G .

Theorem 2.3.10 ► Tutte's Theorem

A graph G has a perfect matching if and only if for every $U \subseteq V(G)$, $o(G - U) \leq |U|$.

Proof. Let $M \subseteq G$ be a perfect matching. Take any $U \subseteq V(G)$ and consider the induced subgraph $H := G - U$. Let $C \subseteq H$ be a connected component of odd order. Since M is a perfect matching, then clearly there is at least one vertex $v \in C$ which is matched to some vertex $u \in U$ in M . Since every $u \in U$ is matched to exactly one vertex in M , this implies that $o(H) \leq |U|$.

Suppose conversely that for every $U \subseteq V(G)$, $o(G[V(G) - U]) \leq |U|$. We shall prove that G contains a perfect matching by considering the contrapositive statement. Let $v(G) = n$. First, we consider the following lemma:

Lemma 2.3.11

If graphs $G \subseteq G'$ are such that $V(G) = V(G')$ but $E(G) \subsetneq E(G')$, then if $U \subseteq V(G')$ is such that $o(G' - U) > |U|$, we have $o(G - U) > |U|$.

Proof. Note that G is produced by deleting some edges in G' . For each edge $e \in E(G') - E(G)$, if e is in an odd component $H_1 \subseteq G'$, then $H_1 - e$ contains at least one odd component in G . Otherwise, if e is in an even component $H_2 \subseteq G'$, then $H_2 - e$ may or may not contain any odd component. Therefore, we have

$$o(G - U) \geq o(G' - U) > |U|.$$

\square

By Lemma 2.3.11, without loss of generality we can take G to be the edge-maximal graph of order n such that G does not contain any perfect matching.

Consider $U := \{v : v \sim u \text{ for all } u \in V(G) - v\}$, i.e., U consists of vertices in G which are adjacent to every other vertex in G , then $G[U]$ is a clique. We claim that every connected component of $G - U$ is complete. Suppose on contrary that there is some connected component $C_i \subseteq G - U$ which is not complete, then there exists distinct vertices $a, a' \in V(C_i)$ such that $a \not\sim a'$. Therefore, there exists an a - a' path in C_i of length at least 2, and so we can find vertices $a, b, c \in V(C_i)$ such that $a \sim b$, $b \sim c$ but $a \not\sim c$. Note that $b \notin U$, so there exists some $d \in V(G)$ such that $b \sim d$.

Define graphs $G_1 := G + ac$ and $G_2 := G + bd$. By the edge-maximality of G , G_1 contains a perfect matching M_1 and G_2 contains a perfect matching M_2 . Note that $ac \in E(M_1)$, because otherwise M_1 is a perfect matching with vertex set $V(G)$ and edge set $E(G)$, which is not possible. Similarly, $bd \in E(M_2)$. Let $P \subseteq G$ be a maximal d - v path for some $v \in V(G)$ which is alternating between edges in M_1 and M_2 .

Suppose P ends with an M_1 -edge, then v must be matched to d in M_2 because otherwise we can find a longer M_1 - M_2 alternating path than P , which is not possible. Since $bd \in E(M_2)$, this implies that $v = b$. Note that $M_1 \cap P \subseteq G$ is a perfect matching in P and $M_2 - P - bd$ is a perfect matching in $G - P$, then $(M_1 \cap P) \cup (M_2 - P - bd)$ is a perfect matching in G .

Similarly, suppose P ends with an M_2 -edge, then v must be either a or c , because otherwise there exists an edge $uv \in E(M_1) \cap E(G)$ that can further extend P , which is not possible. Without loss of generality, suppose $v = c$, then it is clear that $a \notin P$. We claim that $b \notin P$. Suppose on contrary that $b \in P$, then there must be an M_1 edge in P containing b because there is no M_2 edge in P containing b . However, this means that P ends with an M_2 edge, which is a contradiction. Note that $M_2 \cap P \subseteq G$ is a perfect matching in P and $M_1 - P - ac + ab$ is a perfect matching in $G - P$. Therefore, $(M_2 \cap P) \cup (M_1 - P - ac + ab)$ is a perfect matching in M .

Either way, we have reached a contradiction because M does not contain any perfect matching. Therefore, every connected component of $G - U$ is complete. If $U = \emptyset$, then $G - U = G$ is complete. Since G has no perfect matching, $v(G)$ must be odd and so $o(G - U) = 1 > 0 = |U|$. Otherwise, for each connected component $C_i \subseteq G$, if C_i has an even order, it contains a perfect matching. Otherwise, C_i has an odd order. Take some $v_i \in V(C_i)$ and match it to some $u_i \in U$. Note that $C_i - v_i$ is a complete graph of even order and so it contains a perfect matching. Ho \square

Tutte's Theorem has many interesting applications, one of which is related to the concept

of an *cut edge* or *cut vertex*.

Theorem 2.3.12 ► Petersen's Theorem

Every connected 3-regular graph with no cut edge contains a perfect matching.

Proof. Let $U \subseteq V(G)$ be non-empty and consider $H := G - u$. If H contains no odd-order component, then we are done. Otherwise, fix some odd-order component $C \subseteq H$. Consider

$$\sum_{v \in V(C)} d_G(v) = 3|C| = 2e(G[V(C)]) + e_G(V(C), U).$$

Note that the above sum is odd, so $e_G(V(C), U)$ is odd. Since G contains no cut-edge, $e_G(V(C), U) \geq 3$. Let p be the number of odd components in $G - u$ and M be the number of edges between U and $V(G) - U$, then $M \geq 3p$. However, $M \leq 3|U|$ because G is 3-regular, so $p \leq |U|$. By Theorem 2.3.10, G contains a perfect matching. \square

Note that a graph $G = (V, E)$ can actually be viewed as a collection of 2-element subsets of V . Therefore, a natural generalisation is to consider a graph defined as the collection of subsets of any size of V .

Definition 2.3.13 ► Hypergraph

Let V be a vertex set, a **hypergraph** on V is a graph whose edge set is a family

$$E := \{X : X \subseteq \mathcal{P}(V)\}.$$

If $|X| = k$ for all $X \in E$, we say that the hypergraph is k -uniform.

Connectivity

3.1 Vertex Connectivity

Recall that in previous chapters, we have already defined what a *connected graph* is (Definition 1.2.4). However, intuitively, we may feel that graphs may have varying degrees of “connectedness”. For example, a complete graph seems more connected than a path, since one could easily disconnect a path by deleting $\mathcal{O}(1)$ vertices but needs to delete $\mathcal{O}(n)$ vertices to disconnect K_n .

In this chapter, we probe further into the notion of connectivity. In particular, we would like to discuss the strength of connectedness in a graph.

Definition 3.1.1 ▶ Separating Set

Let G be a connected graph. $S \subseteq V(G)$ is a **separating set** (or **vertex cut**) of G if $G - S$ is disconnected. If $S = \{s\}$ is a singleton, then s is known as a **cut vertex**.

Separating set provides an intuitive measure for how connected a graph really is. Obviously, any finite graph must have only finitely many different separating set. Naturally, we could consider the size of the smallest separating set as an indicator for the amount of deletion needed to disconnect the graph.

Definition 3.1.2 ▶ Vertex Connectivity

The **vertex connectivity** of a graph G , denoted by $\kappa(G)$ is the cardinality of the smallest subset $S \subseteq V(G)$ such that $G - S$ is either disconnected or a trivial graph. G is said to be **k -connected** if $\kappa(G) \geq k$.

Obviously, $\kappa(G) \leq v(G) - 1$ for any graph G , and a k -connected graph must be $(k - 1)$ -connected. Our “old-fashioned” notion of a connected graph is simply a 1-connected graph. As usual, let us examine some special graphs as examples.

1. Complete graph K_n : $\kappa(K_n) = n - 1$.
2. Path P_n : $\kappa(P_n) = 1$.
3. Non-trivial cycle C_n : $\kappa(C_n) = 2$.
4. Complete bipartite graph $K_{m,n}$: $\kappa(K_{m,n}) = \min\{m, n\}$.

We may also wish to consider the hypercube graph Q^d . Intuitively, Q^d is d -regular, so it suffices to fix any $v \in V(Q^d)$ and delete all of its d neighbours to isolate the vertex. Therefore, $\kappa(Q^d) \leq d$. However, can we force the inequality to an equality?

Proposition 3.1.3 ▶ The Hypercube Graph Q^d is d -connected

Every hypercube graph Q^d is d -connected.

Proof. The case where $d = 1$ is trivial. Suppose that for some $d \in \mathbb{N}^+$, Q^d is d -connected. Consider Q^{d+1} . Notice that $Q^{d+1} = Q^+ \cup Q^- \cup M$, where Q^+ and Q^- are both Q^d and M is a perfect matching joining vertices in Q^+ and those in Q^- with exactly 1 different digit. Let S be the smallest vertex cut in Q^{d+1} . We consider 2 cases.

If $Q^+ - S$ and $Q^- - S$ are both connected, then $V(M) \subseteq S$ because otherwise there is an edge between $Q^+ - S$ and $Q^- - S$ in $Q^{d+1} - S$ and so $Q^{d+1} - S$ is connected, which is a contradiction. Therefore,

$$\kappa(Q^{d+1}) = |S| \geq |M| = 2^d \geq d + 1.$$

Otherwise, without loss of generality assume that Q^+ is disconnected, then $S \cap Q^+$ is a vertex cut in Q^+ . By the inductive hypothesis, $|S \cap Q^+| \geq d$. We claim that $|S \cap Q^-| \geq 1$. Suppose on contrary that $|S \cap Q^-| = 0$, then $S \cap V(Q^-) = \emptyset$. This means that $Q^- - S$ is connected. Note that for every $v \in V(Q^+ - S)$, there exists some $u \in V(Q^- - S)$ such that $uv \in E(Q^{d+1} - S)$, because otherwise $S \cap V(Q^-) \neq \emptyset$. Therefore, for any $v_1, v_2 \in V(Q^+ - S)$, we can find $u_1, u_2 \in V(Q^- - S)$ such that there is a $v_1 - v_2$ path in Q^{d+1} containing $v_1 u_1$ and $v_2 u_2$. Therefore, $Q^{d+1} - S$ is connected, which is a contradiction. Therefore,

$$\kappa(Q^{d+1}) = |S| = |S \cap Q^+| + |S \cap Q^-| \geq d + 1.$$

This means that Q^{d+1} is $(d + 1)$ -connected. □

Next, we will focus on 2-connected graph, i.e., graphs which we need to delete at least 2 vertices to disconnect. We will start with a straight-forward proposition.

Proposition 3.1.4 ▶ 2-connected Graphs Contain A Cycle

Every 2-connected graph contains a cycle.

Proof. Suppose on contrary that there exists a 2-connected graph T which is acyclic. Note that T is connected, so T must be a tree. By Theorem 1.4.2, $T - uv$ is disconnected for any $uv \in E(T)$. If both u and v are leaves, then T is an edge, which implies that

deleting any vertex reduces T to a trivial graph. Otherwise, without loss of generality, assume u is not a leaf, and so $T - u$ is disconnected. Either way, this contradicts with the fact that $\kappa(T) \geq 2$. \square

It should be taken note of that the converse of Proposition 3.1.4 is not true in general. Let C_n be a cycle, then adding a vertex v into C_n by joining it with any $u \in V(C_n)$ produces a graph H containing a cycle. However, $H - u$ is disconnected so $\kappa(H) = 1$.

An intuition about connectivity is that, if we were to increase the connectivity of a graph, we should try to make each vertex to have as many incident edges as possible.

Proposition 3.1.5 ► High Connectivity Implies High Minimum Degree

For any graph G , $\kappa(G) \leq \delta(G)$.

Proof. Take some $v \in V(G)$ with $d_G(v) = \delta(G)$, then clearly $N_G(v)$ is a vertex cut because v is an isolated vertex in $G - N_G(v)$, and so $\kappa(G) \leq |N_G(v)| = \delta(G)$. \square

The above trivial proposition shows that a graph with high connectivity has high minimum degree. However, the converse is clearly not true. Consider the graph G formed by 2 disjoint copies of K_n , then clearly $\delta(G) = n - 1$ but $\kappa(G) = 0$, i.e., G is not even connected.

Recall that in Proposition 1.1.13, while we cannot ensure a graph with a high average degree to have a high minimum degree, we have proved that the graph will contain a subgraph of a high minimum degree. In the same spirit, given a graph with a high minimum degree, we can try to find a subgraph with a high connectivity.

Theorem 3.1.6 ► Mader's Theorem

For every graph G , if $\bar{d}(G) \geq 4k$, then G contains a k -connected subgraph.

Proof. For $k = 1$, we have $\bar{d}(G) \geq 4$. This means that G is non-empty and so it contains an edge which is a 1-connected subgraph.

For $k \geq 2$, we consider the following claims: first, suppose $v(G) < 2k - 1$, then $\bar{d}(G) \leq v(G) - 1 < 2k - 2$. Therefore, if $\bar{d}(G) \geq 4k > 2k - 2$, we have $v(G) \geq 2k - 1$. On the other hand, notice that

$$e(G) = \frac{v(G)\bar{d}(G)}{2} \geq (2k - 3)(v(G) - k + 1) + 1.$$

Therefore, it suffices to prove that whenever $k > 2$, if $v(G) \geq 2k - 1$ and $e(G) \geq (2k - 3)(v(G) - k + 1) + 1$, then G contains a k -connected subgraph.

For $v(G) = 2k - 1$, we have

$$e(G) \geq k(2k - 3) + 1 = (2k - 1)(k - 1) = \binom{2k - 1}{2}.$$

However, we know that $e(G) \leq \binom{v(G)}{2}$, so $G \cong K_{2k-1}$. Therefore, $\kappa(G) = 2k - 2 \geq k$ and so G is k -connected.

For $v(G) = n \geq 2k$, suppose that for all $v(G) = m \in [2k - 1, n - 1]$, G contains a k -connected subgraph. We consider 2 cases. If $\delta(G) \leq 2k - 3$, then we can take some $v \in V(G)$ with $d_G(v) = \delta(G)$. Consider

$$\begin{aligned} e(G - v) &= e(G) - \delta(G) \\ &\geq (2k - 3)(n - k + 1) + 1 - (2k - 3) \\ &= (2k - 3)((n - 1) - k + 1) + 1. \end{aligned}$$

By the inductive hypothesis, $G - v$ contains a k -connected subgraph H . Since $G - v \subseteq G$, $H \subseteq G$.

If $\delta(G) \geq 2k - 2 > 2k - 3$, we again consider 2 cases. If G is k -connected, then we are done. Otherwise, G contains a vertex cut with size at most $k - 1$. Therefore, we can consider $G_1, G_2 \subseteq G$ such that $G_1 \cup G_2 = G$ and $V(G_1) \cap V(G_2)$ is a vertex cut such that $|V(G_1) \cap V(G_2)| \leq k - 1$. Notice that this implies that there is no edge between $V(G_1) - V(G_2)$ and $V(G_2) - V(G_1)$. Consider any $v \in V(G_1)$. Note that $N_G(v) \subseteq V(G_1)$ and $d_G(v) \geq \delta(G) \geq 2k - 2$, so $|V(G_1)| \geq d_G(v) + 1 = 2k - 1$. Similarly, $|V(G_2)| \geq 2k - 1$. Suppose that

$$\begin{aligned} e(G_1) &\leq (2k - 3)(v(G_1) - k + 1), \\ e(G_2) &\leq (2k - 3)(v(G_2) - k + 1), \end{aligned}$$

then

$$\begin{aligned} e(G) &\leq e(G_1) + e(G_2) \\ &\leq (2k - 3)(v(G_1) + v(G_2) - 2k + 2) \\ &= (2k - 3)(n + |V(G_1) \cap V(G_2)| - 2k + 2) \\ &\leq (2k - 3)(n + k - 1 - 2k + 2) \\ &= (2k - 3)(n - k + 1), \end{aligned}$$

which is a contradiction. Therefore, without loss of generality, we have

$$e(G_1) \geq (2k - 3)(v(G_1) - k + 1) + 1.$$

Therefore, by the inductive hypothesis, G_1 contains a k -connected subgraph H . Since $G_1 \subseteq G$, $H \subseteq G$. Therefore, any graph G with $\bar{d}(G) \geq 4k$ contains a k -connected subgraph. \square

Since a high minimum degree implies a high average degree, Theorem 3.1.6 in fact guarantees that a graph with a high minimum degree will have a high connectivity.

3.2 Edge Connectivity

Since we can measure connectivity in terms of the minimum number of vertices which need to be deleted to disconnect a graph, it is only natural to consider from the perspective of edges.

Definition 3.2.1 ► Edge Connectivity

A graph G is said to be **ℓ -edge-connected** if for any $F \subseteq E(G)$ with $|F| < \ell$, $G - F$ is connected. The **edge connectivity** of G , denoted by $\kappa'(G)$, is defined as the size of the smallest subset $F \subseteq E(G)$ such that $G - F$ is disconnected.

Similar to separating sets, we can analogously define a set of edges which will disconnect the graph when removed.

Definition 3.2.2 ► Disconnecting Set

Let G be a graph, a set $F \subseteq E(G)$ is called a **disconnecting set** if $G - F$ is disconnected.

However, as opposed to vertex cuts, the notion of an *edge cut* is slightly different.

Definition 3.2.3 ► Edge Cut

Let G be a graph and (S, \bar{S}) be a partition for $V(G)$, an **edge cut** in G with respect to (S, \bar{S}) is defined as

$$E_G(S, \bar{S}) := \{xy \in E(G) : x \in S, y \in \bar{S}\}.$$

If an edge cut contains only a single edge, that edge is known as a **cut edge** or **bridge**.

Intuitively, any edge set is a disconnecting set, but not every disconnecting set is an edge

cut. However, it turns out that every **minimal disconnecting set** is an edge cut! Let us do the routine examination on the special graphs.

1. Complete graph K_n : $\kappa'(K_n) = n - 1$.
2. Path P_n : $\kappa'(P_n) = 1$.
3. Non-trivial cycle C_n : $\kappa'(C_n) = 2$.
4. Complete bipartite graph $K_{m,n}$: $\kappa'(K_{m,n}) = \min\{m, n\}$.
5. Hypercube graph Q^d : $\kappa'(Q^d) = d$.

Notice that in all of these examples, $\kappa = \kappa'$. If for any graph G , $\kappa(G) = \kappa'(G)$, things will not be very interesting. However, this is luckily not the case. Consider a graph formed by 2 complete graphs of order n with exactly one common vertex. One may check that we only need to remove the shared vertex to disconnect the graph but need to delete at least $(n - 1)$ edges to do the same.

In fact, we can derive the following relation:

Proposition 3.2.4 ► Numerical Relationship between Connectivities

For every graph G , $\kappa(G) \leq \kappa'(G) \leq \delta(G)$.

Proof. If G is disconnected, the result is trivial.

Otherwise, let $v \in V(G)$ be such that $d_G(v) = \delta(G)$. Note that deleting all edges incident to v will isolate the vertex, so $\kappa'(G) \leq \delta(G)$.

Let $E(S, \bar{S})$ be an edge cut with $|E(S, \bar{S})| = \kappa'(G)$. We consider 2 cases. If $E(S, \bar{S})$ induces a complete graph, then

$$\begin{aligned} \kappa'(G) &= |S||\bar{S}| \\ &= |S|(v(G) - |\bar{S}|) \\ &\geq v(G) - 1 \\ &\geq \kappa(G). \end{aligned}$$

Otherwise, there exist some $x \in S$ and $y \in \bar{S}$ such that $xy \notin E(S, \bar{S})$. Define

$$U := N_G(x) \cap \bar{S} \cup \{v \in S - \{x\} : N_G(v) \cap \bar{S} \neq \emptyset\}.$$

Consider $H := G - U$. Notice that there is no x - y path in H because $E_H(S - U, \bar{S}) = \emptyset$.

Therefore, H is disconnected and so U is a vertex cut. Therefore,

$$\kappa(G) \leq |U| \leq |S| \leq |E(S, \bar{S})| = \kappa'(G).$$

Therefore, $\kappa(G) \leq \kappa'(G) \leq \delta(G)$. □

Remark. Note that there exists some graph G with $\kappa(G) < \kappa'(G) < \delta(G)$.

Lastly, we will state the following theorem without proof:

Theorem 3.2.5 ► Chartrand-Harary Theorem

For all positive integers a, b, c with $a \leq b \leq c$, there exists a graph G with $\kappa(G) = a$, $\kappa'(G) = b$ and $\delta(G) = c$.

3.3 Blocks

We know that every graph can be naturally decomposed into connected components. However, can we actually present a stronger definition? Here, we consider components of a graph that are 2-connected.

Definition 3.3.1 ► Block

For any graph G , a **block** in G is defined as a maximal connected subgraph $B \subseteq G$ without any cut vertex.

Remark. We define an edge K_2 and a trivial graph both as blocks.

Let us make some observations regarding the properties of a block.

First, observe that a block is either an isolated vertex, a cut edge or a 2-connected graph. Next, we shall characterise the vertices of blocks.

Proposition 3.3.2 ► Blocks Share at Most One Common Vertex

Let B_i and B_j be distinct blocks of G , then $|V(B_i) \cap V(B_j)| \leq 1$.

Proof. Suppose on contrary that $|V(B_i) \cap V(B_j)| \geq 2$. Consider $B := B_i \cup B_j$. Note that for any vertex $v \in V(B_i) \triangle V(B_j)$, v is not a cut vertex of B . Take any $u_1, u_2 \in V(B_i) \cap V(B_j)$ and consider $B - u_1$. Let $w_1, w_2 \in V(B - u_1)$ be any vertices. If $w_1, w_2 \in V(B_i)$ or $w_1, w_2 \in V(B_j)$, then they are connected in $B - u_1$. Otherwise, without loss of

generality, assume $w_1 \in V(B_i) - V(B_j)$ and $w_2 \in V(B_j) - V(B_i)$. Note that there exist a u_2-w_1 path and a u_2-w_2 path in $B - u_1$, so w_1 and w_2 are connected in $B - u_1$. Therefore, B does not have a cut vertex and so is a block, but $B_i, B_j \subset B$, which is a contradiction. \square

The above result allows us to show the following corollary about the edges in a graph with respect to its blocks:

Corollary 3.3.3 ▶ Every Edge Is in A Unique Block

Let G be a graph. Every $e \in E(G)$ is in a unique block of G .

Proof. First, notice that every edge is a connected subgraph of G without any cut vertex, so any edge $e \in E(G)$ must be in some block of G . Suppose on contrary that there exist distinct blocks $B_i, B_j \subseteq G$ such that $e \in E(B_i) \cap E(B_j)$, then $|V(B_i) \cap V(B_j)| \geq 2$, which contradicts Proposition 3.3.2. \square

By the above corollary, we know that no two different blocks can share common edges.

It is clear that every graph can be decomposed into blocks. We would like to further study block decomposition and hopefully derive a relation between the structure of blocks and that of the graph itself.

Definition 3.3.4 ▶ Block Graph

Let G be a graph. Define \mathcal{A} to be the set of cut vertices of G and \mathcal{B} to be the set of blocks in G . A **block graph** on G is a bipartite graph with bipartition $(\mathcal{A}, \mathcal{B})$ such that a cut vertex $a \in \mathcal{A}$ is adjacent to $B \in \mathcal{B}$ if $a \in V(B)$.

Block graph might be a bit abstract to visualise. To better understand its structure, let us consider the following result:

Proposition 3.3.5 ▶ A Block Graph on A Connected Graph Is A Tree

Let T be a block graph of a connected graph G , then T is a tree.

Proof. Take any $B_1, B_n \in \mathcal{B}$. Note that there exists a sequence $(B_1, B_2, \dots, B_{n-1}, B_n)$ of blocks in G such that B_i and B_{i+1} share a common vertex. Denote this vertex as v_i , then clearly, v_i is adjacent to B_i and B_{i+1} in T . Therefore, $B_1 v_1 B_2 v_2 \dots B_{n-1} v_{n-1} B_n$ is a B_1 - B_n walk in T , and so B_1 and B_n are connected. Take any $a \in \mathcal{A}$ and any $B \in \mathcal{B}$. Note that there exists some $B' \in \mathcal{B}$ such that $a \sim B'$. Since B and B' are connected, a and B are connected. Similarly, one can check that any $a, a' \in \mathcal{A}$ are connected in T . Therefore, T is connected.

We will proceed to proving that T is acyclic by contradiction. Suppose on contrary that T contains a cycle. Without loss of generality, we can re-label the vertices such that the cycle is in the form of $a_1B_1a_2B_2 \cdots a_nB_na_{n+1}$ with $a_1 = a_{n+1}$. This means that for any integer $k \in [1, n]$, $a_k, a_{k+1} \in V(B_k)$ and that $V(B_{k-1}) \cap V(B_k) = a_k$ whenever $k \geq 2$. Consider $B = \bigcup_{i=1}^n B_i$. Notice that B is connected and does not have any cut vertex, so B is a block in G . However, for any of the B_i 's, $B_i \subset B$, which contradicts the maximality of B_i . Therefore, T is acyclic, which implies that T is a tree. \square

To summarise, we see that for any connected graph G , its block graph is a tree such that every $B \in \mathcal{B}$ is either an edge or a 2-connected graph.

We introduce a useful definition which will help us investigate the structure of 2-connected graphs later.

Definition 3.3.6 \blacktriangleright H -path

Let G be a graph with a subgraph H . An **H -path** is a path P in G such that its 2 ends are the only vertices in $P \cap H$.

Recall that in Proposition 3.1.4, we have shown that every 2-connected graph contains a cycle, but that the converse is not true. However, can we try to extend from this necessary condition somehow to give a more precise characterisation of a 2-connected graph?

Theorem 3.3.7 \blacktriangleright Ear-Decomposition

A graph G is 2-connected if and only if it can be constructed from a cycle by successively augmenting the partially constructed graph H with H -paths.

Proof. Suppose that G is constructed from a cycle by successively augmenting H -paths to a partially constructed graph H . Note that a cycle is 2-connected. Assume that there exists some $k \in \mathbb{N}$ such that after k iterations of such augmentation, the resulted graph H is 2-connected. Consider $H' := H \cup P_H$ where P_H is any H -path, the clearly H' is also 2-connected. Therefore, G must be 2-connected.

Suppose conversely that G is 2-connected, then by Proposition 3.1.4 it contains a cycle C_n . Therefore, G contains a maximal subgraph H which can be constructed by augmenting H -paths successively to a partially constructed graph starting from C_n . Note that it suffices to show that $G = H$.

We claim that H must be an induced subgraph of G . Suppose on contrary that

there exists $u, v \in V(H)$ such that $uv \in E(G)$ but $uv \notin E(H)$, then clearly uv itself is an H -path in G . Therefore, $H + uv$ is a larger graph constructible from C_n by successively augmenting H -paths to the partially constructed graph, which is a contradiction because H is assumed to be maximal.

Suppose on contrary that $G \neq H$, then $V(G) - V(H) \neq \emptyset$. Note that G is connected, so there exist $v \in V(G) - V(H)$ and $w \in V(H)$ such that $vw \in E(G)$. Note that $C_n \subseteq H$, so there exists some $u \in V(H)$ with $u \neq w$. Since G is 2-connected, we know that $G - w$ is connected. This implies that there is a v - u path in G which does not contain w . Without loss of generality, let u' be the first vertex in the path which is in $V(H)$, then we have found a v - u' path which is an H -path. This means we can construct a larger graph H' by augmenting the H -path to H , which contradicts the maximality of H . \square

An H -path is vividly termed as an “ear” to the graph. Clearly, Theorem 3.3.7 shows that any 2-connected graph can be decomposed into a cycle and a series of H -paths. This is thus also known as the “ear-decomposition” of G .

We would like to take one step further and probe into 3-connected graphs. We will state the following theorem by Tutte without proof:

Theorem 3.3.8 ► Tutte’s Characterisation of 3-connected Graphs

A graph G is 3-connected if and only if there is a sequence (G_0, G_1, \dots, G_n) with $G_n \cong G$ such that $G_0 = K_4$ and G_{i+1} contains an edge xy with $d_{G_{i+1}}(x), d_{G_{i+1}}(y) \geq 3$ and $G_i = G_{i+1} \circ xy$.

Ear-decomposition is a fairly nice construction for a 2-connected graph. However, as a characterisation it is not very intuitive, in a sense that one still needs to work towards the graph from a cycle to actually verify 2-connectivity. Can we do better and propose a more direct characterisation?

Theorem 3.3.9 ► Whitney’s Characterisation of 2-connected Graphs

A graph G is 2-connected if and only if for every $u, v \in V(G)$, there exist 2 internally disjoint u - v paths in G .

Here, “internally disjoint” paths means that the paths share no other vertices except u and v . More generally, we define the following:

Definition 3.3.10 ▶ A - B Path

Let G be a graph with $A, B \subseteq V(G)$. An **A - B path** is a path in G which contains exactly one vertex in A and one vertex in B .

Note that in the above definition, we do not require A and B to be disjoint. Clearly, if $A \cap B \neq \emptyset$, then every vertex in $A \cap B$ is a trivial A - B path. Intuitively, to disconnect G , we necessarily need to disconnect A and B , i.e., we need to make sure that there is no A - B path in G .

Definition 3.3.11 ▶ Separating Set for (A, B)

Let G be a graph with $A, B \subseteq V(G)$. A **separating set** for (A, B) is a set X consisting of both edges and vertices such that there is no A - B path in $G - X$.

Notice that we have not given the proof for Theorem 3.3.9 yet. One may choose to use ear-decomposition to prove the theorem, but we can also see it as a corollary of another theorem. However, before proving the actual theorem, we first consider the following lemma:

Lemma 3.3.12 ▶ A - B Paths Extension

Let G be a graph with $A, B \subseteq V(G)$ such that the minimum separating set for (A, B) has size k , then for any set P of less than k vertex-disjoint A - B paths in G , there is a set Q of vertex-disjoint A - B paths in G whose set of end vertices contains the set of end vertices in P as a proper subset.

Proof. Fix any $A \subseteq V(G)$. We will perform induction on $|V(G)| - |B|$. Note that when $|V(G)| - |B| = 0$, we have $B = V(G)$ and so $k = |A|$. If $|P| < k$, then there is at least one vertex $a \in A$ which is not contained by any path in P . Take $Q := P \cup \{a\}$ then Q is a set of $|P| + 1$ vertex disjoint A - B paths in G whose set of end vertices contains the end vertices in P as a proper subset.

Take any $A, B \subseteq V(G)$ and fix $P := \{P_1, P_2, \dots, P_n\}$ to be a set of $n < k$ vertex-disjoint A - B paths. We denote the set of end vertices in P by $P_A := \{a_1, a_2, \dots, a_n\}$ and $P_B := \{b_1, b_2, \dots, b_n\}$. Clearly, P_B is not a separating set for (A, B) , so there is some A - B path which does not contain any vertex from P_B . Let this path be R with end vertex $b_R \in B$. If R is vertex-disjoint to every $P_i \in P$, then we are done.

Otherwise, $R \cap P_j \neq \emptyset$ for some $P_j \in P$. Without loss of generality, let $x \in V(R)$ be the vertex such that the x - b_R path in R contains no vertex from P , i.e., x is the last intersection between R and the paths in P . Without loss of generality, we

can re-label the paths in P such that $x \in P_n$. Denote by xR the x - b_R path in R and by xP_n the x - b_n path in P_n . Define $B' := B \cup V(xR) \cup V(xP_n)$, then $B \subsetneq B'$ and so $|V(G)| - |B'| < |V(G)| - |B|$. Let $P' := \{P_1, P_2, \dots, P_{n-1}, P_n x\}$, then P' is a set of n vertex-disjoint A - B' paths in G . Now, take any X to be a minimum separating set for (A, B') , then clearly X separates (A, B) , so $|X| \geq k > n$. By the inductive hypothesis, we can find a set Q' of vertex-disjoint A - B' paths in G such that the set of end vertices of Q' contains the end vertices of P as a proper subset.

Let $P'_{B'} := \{b_1, b_2, \dots, b_{n-1}, x\}$ be the set of end vertices in B' for paths in P' . Let $Q' := \{Q'_1, Q'_2, \dots, Q'_{n+1}\}$ and denote the end vertex of Q'_i in B by $B(Q'_i)$, then without loss of generality, we can re-label the vertices such that

$$B(Q'_i) = \begin{cases} b_i & \text{if } i = 1, 2, \dots, n-1 \\ x & \text{if } i = n \\ y & \text{if } i = n+1 \end{cases},$$

where $y \notin P'_{B'}$. Note that $Q'_1, Q'_2, \dots, Q'_{n-1}$ are already vertex-disjoint A - B paths. We will try to extend Q' to obtain Q . We consider 2 cases on y .

If $y \in xP_n$, then every vertex in $V(xR) - \{x\}$ is unused by all paths in Q' , and so we can extend Q'_n by xR to obtain an A - B path, and extend Q'_{n+1} by yP_n to obtain another A - B path. Note that xR and yP_n are vertex-disjoint, so we have obtained a set Q of $(n+1)$ vertex-disjoint A - B paths as desired.

If $y \notin xP_n$, then we can extend Q'_n by xP_n to connect b_n . Note that either $y \in yR$ or $y \in B$, but either way we can extend Q'_{n+1} to a new vertex in B , so we still can obtain Q as desired. \square

Now we are ready to state the following theorem:

Theorem 3.3.13 ► Menger's Theorem

Let G be a graph with $A, B \subseteq V(G)$, then the minimum size of separating sets for (A, B) equals the maximum number of vertex-disjoint A - B paths in G .

Proof. Let X to be a minimum separating set for (A, B) and k to be the number of vertex-disjoint A - B paths in G . Clearly, to disconnect A and B , we need to at least delete either one edge or one vertex from each of the k A - B paths. Therefore, $|X| \geq k$.

Take any $n < |X|$ disjoint A - B paths, then by Lemma 3.3.12, we can extend this set of paths by another vertex-disjoint A - B paths until $n = |X|$. Therefore, $k \geq |X|$, which implies that $k = |X|$ as desired. \square

By taking both sets of vertices as singletons, we obtain a corollary of Theorem 3.3.13 at a “local” level.

Corollary 3.3.14 ► Local Version of Menger’s Theorem

Let G be a graph. If $a, b \in V(G)$ are not adjacent, then

1. the minimum number of vertices which separate a and b when removed equals the maximum number of internally vertex-disjoint a - b paths in G ;
2. the minimum number of edges which separate a and b when removed equals the maximum number of edge-disjoint a - b paths in G .

Proof. Note that the minimum number of vertices that separate a and b when removed is just the minimum number of vertices that separate $N_G(a)$ and $N_G(b)$ when removed. By Theorem 3.3.13, this quantity is just the maximum number of vertex-disjoint $N_G(a)$ - $N_G(b)$ paths in G , which are internally vertex-disjoint a - b paths.

Let $L(G)$ be the line graph of G and let A and B be the sets of edges containing a and b respectively. Then, the minimum number of edges to separate a and b when removed is equal to the minimum number of vertices to separate A and B when removed in $L(G)$. By Theorem 3.3.13, this quantity is just the number of vertex-disjoint A - B paths in $L(G)$, which correspond to edge-disjoint a - b paths in G . \square

Correspondingly, the following “global” version of Menger’s Theorem characterises a k -connected graph, to which Theorem 3.3.9 is an immediate corollary.

Corollary 3.3.15 ► Global Version of Menger’s Theorem

A graph G is k -connected if and only if for any $u, v \in V(G)$, there are k internally vertex-disjoint u - v paths in G . A graph G is k -edge-connected if and only if for any $u, v \in V(G)$, there are k edge-disjoint u - v paths in G .

Proof. Suppose the for any $u, v \in V(G)$, there exist k internally vertex-disjoint u - v paths in G . Let S be a set of less than k vertices in G and consider $G - S$. For any $u, v \in V(G) - S$, we know that there is at least one u - v path in $G - S$, so $G - S$ is connected and so G is k -connected.

Suppose conversely that G is k -connected and suppose on contrary that there exist $a, b \in V(G)$ such that a, b are connected by fewer than k internally vertex-disjoint a - b paths in G . By Corollary 3.3.14, $ab \in E(G)$ because otherwise we can disconnect a and b by deleting fewer than k vertices, which is impossible because G is k -connected. Let $H := G - ab$, then there are at most $(k - 2)$ internally vertex-disjoint a - b paths in H . By Corollary 3.3.14, there exists a set $X \subseteq V(H)$ with $|X| \leq k - 2$ which separates a and b in H . Note that there exists some $w \in V(H) - X - \{a, b\}$ such that X separates w from either a or b in H , because otherwise a and b are connected in $H - X$. Without loss of generality, let X separates w from a .

Note that a and w are connected in $G - X$ because G is k -connected, so there exists at least one a - w path in G which does not contain any vertex in X . Notice that every such path must contain the edge ab because otherwise a and w are connected in $H - X$. Therefore, w and a are disconnected in $G - X - \{b\}$, which means G is $(k - 1)$ -connected, which is a contradiction. \square

With Menger's Theorem, we can prove Theorem 2.3.4 as a corollary. Consider a bipartite graph G with bipartition (A, B) . Add vertices a, b to G to form a new graph H such that $N_H(a) = A$ and $N_H(b) = B$.

Clearly, $\nu(G)$ is the maximum number of internally vertex-disjoint a - b paths in H . By Corollary 3.3.14, this is just the minimum number of vertices which separate a and b in H when removed. Let $X \subseteq V(G)$ be the minimal set of vertices to disconnect a and b when removed, then every a - b path in H must contain a vertex in X . Suppose there is an edge $uv \in E(G)$ such that $u \notin X$ and $v \notin X$, then $auvb$ is an a - b path in $H - X$. Therefore, X is a vertex cover for G and so $\nu(G) = |X| = \tau(G)$.

Graph Colouring

Graph colouring stems from the following simple motivation:

Any map of countries on a plane can be coloured by 4 distinct colours such that no two countries sharing at least one border have the same colour.

The above is summarised as the 4 Colour Theorem. To study such problems, we introduce to notion of graph colouring.

4.1 Vertex Colouring

Definition 4.1.1 ► Proper Colouring

A **proper k -colouring** of a graph G is a mapping

$$c: V(G) \rightarrow \{1, 2, \dots, k\}$$

such that $c(v) \neq c(u)$ whenever $uv \in E(G)$.

Given a graph G with a proper k -colouring c , denote with $V_i := \{v : c(v) = i\}$ the set of all vertices with colour i . Clearly, every V_i is an independent set in G .

Suppose G is bipartite with bipartition (U, V) , then we can colour the vertices in G such that all vertices in U receives one colour and all those in V receives another.

Clearly, if a graph has a proper k -colouring, then it must also have a proper $(k+1)$ -colouring. Therefore, we are interested to know the least number of colours to properly colour a graph.

Definition 4.1.2 ► Chromatic Number

The **chromatic number** of a graph G , denoted as $\chi(G)$, is the smallest positive integer k such that G has a proper k -colouring.

Observe that if $\chi(G) \leq 2$, it is equivalent to saying that we can find a bipartition of $V(G)$, so a bipartite graph can be alternatively defined as a graph G with $\chi(G) \leq 2$.

Furthermore, observe that if $H \subseteq G$, then $\chi(H) \leq \chi(G)$. Consider a cycle C_{2n+1} for some $n \in \mathbb{N}$. It is clear that $\chi(C_{2n+1}) = 3$, so if $C_{2n+1} \subseteq G$, then G cannot be bipartite.

Similar to bipartite graphs, we can define the notion of an r -partite graph with chromatic numbers.

Definition 4.1.3 ▶ r -partite Graph

A graph G is an **r -partite graph** if $\chi(G) \leq r$.

Let us examine some special graphs to see their chromatic numbers:

- Complete graph K_n : $\chi(K_n) = n$.
- Cycle C_n :

$$\chi(C_n) = \begin{cases} 2 & \text{if } 2 \mid n \\ 3 & \text{if } 2 \nmid n \end{cases}.$$

- Empty graph $\overline{K_n}$: $\chi(\overline{K_n}) = 1$.
- Petersen graph P : $\chi(P) = 3$.

Recall the Kneser graph $KG(n, k)$ from Definition 2.2.4. For $i = 2k, 2k + 1, \dots, n$, let V_i be all k -element subsets whose greatest element is i . Note that for any $S, T \in V_i$, we have $i \in S \cap T$ and so $ST \notin E(KG(n, k))$. Therefore, we can colour each V_i using a distinct colour c_i . Notice that in doing so, $(n - 2k + 1)$ colours are used. For any U not in any of the V_i 's, its elements must be from $\{1, 2, \dots, k - 1\}$. By Pigeonhole Principle, this means that the remaining subsets are pair-wise intersecting, and so we can assign an extra colour for all of them. Therefore, $\chi(KG(n, k)) \leq n - 2k + 2$. However, the other direction is not trivial and requires some knowledge of the Borsuk-Ulam Theorem in Topology.

Intuitively, one only needs to construct a proper colouring to establish an upper bound for $\chi(G)$, but to establish the lower bound is not so easy and we often need to do some estimation using other parameters.

Proposition 4.1.4 ▶ Lower Bound of Chromatic Number

For any graph G , $\chi(G) \geq \omega(G)$ and $\chi(G) \geq \frac{|V(G)|}{\alpha(G)}$.

Proof. $\chi(G) \geq \omega(G)$ is trivial and is left to the reader as an exercise.

Fix any proper $\chi(G)$ -colouring for G . For every colour i , the set of vertices

coloured in i , V_i , is an independent set, so $|V_i| \leq \alpha(G)$. Therefore,

$$|V(G)| = \sum_{i=1}^{\chi(G)} |V_i| \leq \chi(G)\alpha(G),$$

and so $\chi(G) \geq \frac{|V(G)|}{\alpha(G)}$. □

An interesting question to ponder is that: do there exist infinitely many pairs of positive integers (k, ℓ) such that $k = \omega(G) < \chi(G) = \ell$? In fact, Lovász proposed a theorem stating that by considering $KG(3k-1, k)$, one can find a triangle-free graph with arbitrarily high chromatic number.

The chromatic number of a graph can be upper-bounded in multiple ways.

Proposition 4.1.5 ▶ Upper Bound of Chromatic Number

For every graph G , $\chi(G) \leq \frac{1}{2} + \sqrt{2|E(G)| + \frac{1}{4}}$.

Proof. Fix a proper $\chi(G)$ -colouring in G . Let V_i and V_j be 2 sets of vertices with colours i and j respectively. Note that there is at least one edge between V_i and V_j , otherwise we can obtain a $(\chi(G)-1)$ -colouring in G , which is not possible. Therefore,

$$|E(G)| \geq \binom{\chi(G)}{2}.$$

Solving the inequality gives $\chi(G) \leq \frac{1}{2} + \sqrt{2|E(G)| + \frac{1}{4}}$. □

This bound is sharp for complete graphs. However, we can use a greedy algorithm to obtain a better bound for many other graphs.

Proposition 4.1.6 ▶ Upper Bound of Chromatic Number by Greedy Algorithm

For any graph G , $\chi(G) \leq \Delta(G) + 1$.

Proof. We can label the vertices in G as v_1, v_2, \dots, v_n and colour them in this order. Fix any colour for v_1 . For any v_i , colour each of its neighbours with the first available colours. If all existing colours are unavailable, we introduce a new colour. Note that for every vertex $v \in V(G)$, its neighbours use at most $d_G(v) \leq \Delta(G)$ distinct colours, so $\chi(G) \leq \Delta(G) + 1$. □

We can further improve this bound by considering the following definition:

Definition 4.1.7 ▶ k -critical Graph

A graph G is said to be **k -critical** if $\chi(G) = k$ and $\chi(G - e) < k$, $\chi(G - v) < k$ for any $e \in E(G)$ and any $v \in V(G)$.

An easy example here is that any odd cycle is 3-critical. In fact, every 3-critical graph must be an odd cycle, which can be proven by a later theorem.

We first examine some properties of k -critical graphs.

Proposition 4.1.8 ▶ Lower Bound of Degrees of k -critical Graphs

For any k -critical graph G , $\delta(G) \geq k - 1$.

Proof. It suffices to prove that $d_G(x) \geq k - 1$ for every $x \in V(G)$. Suppose on contrary that there exists some $v \in V(G)$ such that $d_G(v) < k - 1$. Since G is k -critical, $\chi(G - v) \leq k - 1$ and so there exists a proper $(k - 1)$ -colouring of $G - v$. Note that this means that we can find some colour among these $(k - 1)$ distinct colours to colour v in G such that v does not share the colour with any of its neighbours, which is a contradiction because $\chi(G) = k$. \square

We can establish a better upper bound for chromatic number by using a k -critical graph as follows:

Proposition 4.1.9 ▶ Upper Bound of Chromatic Number By k -critical Subgraph

For every graph G , $\chi(G) \leq 1 + \max_{H \subseteq G} \delta(H)$.

Proof. Note that we can delete vertices and edges from G to obtain a graph G' such that $\chi(G') < \chi(G)$. Therefore, there exists $H \subseteq G$ such that H is $\chi(G)$ -critical. By Proposition 4.1.8, this implies that

$$\chi(G) = \chi(H) \leq \delta(H) + 1 \leq 1 + \max_{H \subseteq G} \delta(H).$$

\square

Remark. Note that $1 + \max_{H \subseteq G} \delta(H) \leq 1 + \max_{H \subseteq G} \Delta(H) = 1 + \Delta(G)$, so this upper bound is stronger than Proposition 4.1.6.

Consider any tree T . Note that T is bipartite and 2-colourable. By Proposition 4.1.9, since any subgraph of T is a forest with a minimum degree of 1, $\chi(G) \leq 2$ is a sharp bound. However, $\Delta(T)$ can be arbitrarily large, which means the bound given by 4.1.6 can be very loose. In fact, we can prove that unless G is a complete graph or an odd cycle, the bound

given by 4.1.6 is always loose.

Theorem 4.1.10 ► Brooks' Theorem

Let G be a connected graph not isomorphic to a complete graph or an odd cycle, then $\chi(G) \leq \Delta(G)$.

Proof. We shall perform strong induction on $|V(G)|$. If $|V(G)| = 1$, then clearly $\chi(G) = 1 = \Delta(G)$. Suppose there is some $n \in \mathbb{Z}^+$ with $n > 1$ such that for any integer $m \in [1, n - 1]$, any graph G with order m is such that $\chi(G) \leq \Delta(G)$.

Suppose on contrary that there exists a graph G' of order n such that $\chi(G') > \Delta(G')$. Take any vertex $v \in V(G')$ and consider $H := G' - v$. Let H' be any connected component of H , then $\Delta(H') \leq \Delta(G')$. If H' is not a complete graph nor an odd cycle, by the inductive hypothesis, $\chi(H') \leq \Delta(H') \leq \Delta(G')$. Otherwise, note that H' will be $\Delta(H')$ -regular. Since at least one vertex in H' is adjacent to v in G' , we have $\chi(H') = \Delta(H') + 1 \leq \Delta(G')$. Therefore, $\chi(H) \leq \Delta(G')$.

Fix a $\Delta(G')$ -colouring on H . Note that $N_{G'}(v) \subseteq V(H)$. We claim that $N_{G'}(v)$ used all $\Delta(G')$ colours, because otherwise we can use one of the $\Delta(G')$ colours to colour v in G' and obtain a $\Delta(G')$ -colouring in G' , which is not possible. Therefore, $d_{G'}(v) = \Delta(G')$, and so every vertex in $N_{G'}(v)$ has a colour distinct to the other neighbours. Let v_i be the neighbour of v coloured in i , and let H_{ij} be the subgraph spanned by all i - and j -vertices in H . We claim that whenever $i \neq j$, v_i and v_j must be in the same connected component C_{ij} of H_{ij} , otherwise, we can interchange all i - and j -vertices in the connected component containing v_i and colour v in i .

Let P be a v_i - v_j path in C_{ij} . Note that $d_H(v_i) = d_{G'}(v_i) - 1 \leq \Delta(G') - 1$. We claim that the neighbours of v_i use exactly $(\Delta(G') - 1)$ distinct colours, otherwise we can re-colour v_i in a different colour and colour v with one of the $\Delta(G')$ colours, which is not possible. This implies that v_i has only one neighbour with colour j , and so the neighbour of v_i in P is its only neighbour in C_{ij} .

We claim that $P = C_{ij}$. Otherwise, take $u \in V(C_{ij})$ to be the vertex closest to v_i such that u is adjacent to at least 3 distinct vertices. Notice that this means that there is a unique v_i - u path in C_{ij} . Note that u has at most $\Delta(G')$ neighbours in H and at least 3 of them are of the same colour. Therefore, the neighbours of u in H are coloured by at most $(\Delta(G') - 2)$ colours. Therefore, we can change u to some other colour such that v_i and v_j belong to different connected components in H_{ij} , which is not possible.

Let i, j, k be distinct colours. We claim that $V(C_{ij}) \cap V(C_{ik}) = \{v_i\}$. Otherwise, let $w \neq v_i$ and $w \in V(C_{ij}) \cap V(C_{ik})$. Note that $d_{C_{ij}}(w) = d_{C_{ik}}(w) = 2$, so the neighbours of w uses at most $(\Delta(G') - 2)$ colours. Similar to the previous claim, this means we can re-colour w such that v_i and v_j are in different connected components, which is not possible.

If $v, v_1, v_2, \dots, v_{\Delta(G')}$ are pair-wise adjacent, then G' must be complete because each C_{ij} is just an edge, which is not possible. Without loss of generality, let $v_1 \sim v_2$ in G' . Consider C_{12} and C_{13} . We first switch all 1-vertices and 3-vertices in C_{13} , and switch all 1-vertices and 2-vertices in $C_{12} - v_1$. Note that the resultant colouring is still proper in H , and now v_2 and v_3 both have colour 1. Therefore, we can colour v in colour 2 to obtain a proper $\Delta(G')$ -colouring of G' , which is a contradiction. \square

Previously in Proposition 4.1.6, we have used a greedy approach to establish that a graph with large chromatic number must have high maximum degree. Intuitively, if a graph contains a clique, its chromatic number is naturally high. However, this is not necessary. In fact, there exists graphs with high girth but also high chromatic number. Moreover, notice that $K_{m,n}$ is 2-colourable, so in fact none of the other graph parameters we have learnt so far can successfully “force” a high chromatic number in a graph.

Here, we devise a construction for a graph with high chromatic number.

Definition 4.1.11 ► Edge Contraction

Let G be a graph. For any $e = xy \in E(G)$, the **edge contraction** of G at e , denoted by G/e , is a graph produced by deleting e and merging x and y such that $N_{G/e}(xy) = N_G(x) \cup N_G(y)$.

We define the notion of a k -constructible graph recursively.

Definition 4.1.12 ► k -constructible Graph

A **k -constructible graph** G for some $k \in \mathbb{Z}^+$ is such that

1. $G \cong K_k$;
2. there is some k -constructible graph H with $x, y \in V(H)$ and $xy \notin E(H)$ such that $G \cong (H + xy)/xy$;
3. there are k -constructible graphs H_1, H_2 with $V(H_1) \cap V(H_2) = \{x\}$ and $y_1x \in E(H_1), y_2x \in E(H_2)$ such that $G \cong H_1 \cup H_2 - y_1x - y_2x + y_1y_2$.

We can easily derive a lower bound for the chromatic number of k -constructible graphs.

Proposition 4.1.13 ► Chromatic Number of k -constructible Graphs

If G is a k -constructible graph, then $\chi(G) \geq k$.

Proof. If $G \cong K_k$, then $\chi(G) = k \geq k$ is trivial.

Suppose $G \cong (H + xy)/xy$ for some k -constructible graph H with $\chi(H) \geq k$, we shall prove that $\chi(G) \geq k$ by considering the contrapositive statement. Suppose that $\chi(G) \leq k - 1$, then we can fix a $(k - 1)$ -colouring in G . Suppose that x and y are contracted into z in G , then we can just colour x and y in H both using the colour of z in G while keep all other vertices the same colour. Since $N_H(x) \cup N_H(y) = N_G(z)$, this colouring is proper in H and so $\chi(H) \leq k - 1$.

Suppose $G \cong H_1 \cup H_2 - y_1x - y_2x + y_1y_2$ for some k -constructible graphs H_1 and H_2 with $V(H_1) \cap V(H_2) = \{x\}$ and $y_1x \in E(H_1), y_2x \in E(H_2)$. We shall prove that if $\chi(H_1) \geq k$ and $\chi(H_2) \geq k$, then $\chi(G) \geq k$ by considering the contrapositive. Suppose that $\chi(G) \leq k - 1$, then we can fix a $(k - 1)$ -colouring in G . Note that $y_1y_2 \in E(G)$, so y_1 and y_2 must have different colours. This means at least one of y_1 and y_2 has a colour distinct from the colour of x . Without loss of generality, assume that x and y_1 have different colours. This means that the colouring of G is still proper in H_1 , and so $\chi(H_1) \leq k - 1$. Therefore, we have proved that any k -constructible graph G is such that $\chi(G) \geq k$. \square

Remarkably, we can use k -constructible graphs to characterise all graphs with a certain chromatic number.

Theorem 4.1.14 ► Hajós's Theorem

For any graph G , $\chi(G) \geq k$ if and only if G has a k -constructible subgraph.

Proof. Suppose G has k -constructible subgraph H . By Proposition 4.1.13, $\chi(H) \geq k$, and so $\chi(G) \geq \chi(H) \geq k$.

Suppose $\chi(G) \geq k$. The case where $k = 1$ is trivial. If $k = 2$, then $\chi(G) \geq 2$ implies that G contains a K_2 which is 2-constructible. For $k \geq 3$, take G to be the edge-maximal graph with $\chi(G) \geq k$ such that G contains not k -constructible subgraph. If G is a complete multi-partite graph, then it contains at least k partite sets. Fix k partite sets in G and take one vertex from each set, then clearly these vertices induce a $K_k \subseteq G$ which is k -constructible.

If G is not complete multi-partite, consider the following lemma:

Lemma 4.1.15 ► Complete Multi-partite Graph Characterisation

Define a graph H with $V(H) = \{x, y, z\}$ and $E(H) = \{yz\}$. A graph G is complete multi-partite if it contains no induced subgraph isomorphic to H .

Proof. If G contains no induced subgraph isomorphic to H , then \overline{G} contains no induced subgraph isomorphic to \overline{H} . Let $G' \subseteq \overline{G}$ be a connected component. Notice that if there are vertices $u, v, w \in V(G')$ such that $u \sim v$ and $v \sim w$, then $u \sim w$ because otherwise $\{u, v, w\}$ induces a $P_2 \cong \overline{H}$ in G' . Therefore, adjacency is a transitive relation on $V(G')$. For any $x, y \in V(G')$, there exists an x - y path in G' . By transitivity, this means that $x \sim y$ in G' . Therefore, G' is a clique. This means that \overline{G} is the union of disjoint cliques, and so G must be complete multi-partite. \square

By Lemma 4.1.15, we know that G must contain some subgraph of order 3 with vertex set $\{x, y_1, y_2\}$ and edge set $\{y_1 y_2\}$. For $i = 1, 2$, let $G_i := G + xy_i$. Since G is edge-maximal with respect to not having k -constructible subgraphs, G_i must contain a k -constructible subgraph H_i . We claim that $xy_i \in E(H_i)$, because otherwise $H_i \subseteq G$, which is not possible. Let H'_1 and H'_2 be copies of H_1 and H_2 and define a graph $H := H'_1 \cup H'_2$. For every vertex $z \in V(H_1) \cap V(H_2)$ with $z \neq x$, let z_1, z_2 be its copy in H'_1 and H'_2 respectively, then $z_1 z_2 \notin E(H)$. Therefore, $V(H'_1) \cap V(H'_2) = \{x\}$ and $xy_1 \in E(H'_1)$, $xy_2 \in E(H'_2)$. Therefore, $H' := H - xy_1 - xy_2 + y_1 y_2$ is k -constructible. Note that for every pair $(z_1, z_2) \in V(H')^2$, $z_1 z_2 \notin E(H')$, and so $(H + z_1 z_2)/z_1 z_2$ is k -constructible. After contracting all (z_1, z_2) 's, we have restored the graph $H_1 \cup H_2 \subseteq G$, which is k -constructible. \square

Theorem 4.1.14 leads to an important property of k -critical graphs.

Corollary 4.1.16 ► k -critical Graphs Are k -constructible

A graph G is k -constructible if it is k -critical.

Proof. Let $H \subseteq G$ be the maximal k -constructible subgraph of G . It suffices to prove that $H = G$. Suppose on contrary that $H \neq G$, then there exists either an edge e or a vertex v in $G - H$. Therefore, $H \subseteq G - e$ and $H \subseteq G - v$, which implies that $\chi(G - e) = \chi(G - v) = k$ by Theorem 4.1.14, which is a contradiction because G is k -critical. \square

4.2 Edge Colouring

Just like vertices, we can also colour the edges of a graph.

Definition 4.2.1 ▶ Edge Colouring

Let G be a graph. A **proper k -edge-colouring** on G is a map $c : E(G) \rightarrow \{1, 2, \dots, k\}$ such that if $|e \cap f| \geq 1$, then $c(e) \neq c(f)$. The minimum k such that G has a proper k -edge-colouring is known as the **edge chromatic number** of G , denoted by $\chi'(G)$.

Intuitively, colouring the edges in a graph is equivalent to colouring the vertices in its line graph, so the following proposition is intuitive:

Proposition 4.2.2 ▶ Chromatic Number of Line Graphs

For any graph G , $\chi'(G) = \chi(L(G))$.

Fix any proper edge-colouring in a graph G , then intuitively, the set of all edges in the same colour forms a matching in G , so one may choose to view $\chi'(G)$ as the minimum number of matchings to decompose G . For example, for a complete graph K_n , we know that $\nu(K_n) = \left\lfloor \frac{n}{2} \right\rfloor$, so

$$\chi'(K_n) \geq \frac{C_2^n}{\left\lfloor \frac{n}{2} \right\rfloor} = \frac{n(n-1)}{2 \left\lfloor \frac{n}{2} \right\rfloor} = \begin{cases} n-1 & \text{if } n \text{ is even} \\ n & \text{otherwise} \end{cases}.$$

Obviously, if $d_G(v) = \Delta(G)$ for some vertex in a graph G , then all edges incident to v in G induce a clique of order $\Delta(G)$ in $L(G)$. By Proposition 4.2.2, this means that

$$\chi'(G) = \chi(L(G)) \geq \Delta(G).$$

Recall that according to Corollary 2.3.9, every d -regular bipartite graph G can be decomposed into d perfect matchings. If we assign each of these perfect matchings a colour, we essentially obtain a proper edge colouring in G . Clearly, in this case $\chi'(G) = d = \Delta(G)$. In fact, this equality can be extended to any bipartite graph.

Theorem 4.2.3 ▶ König's Edge Colouring Theorem

If G is a bipartite graph, then $\chi'(G) = \Delta(G)$.

Proof. It suffices to prove that $\chi'(G) \leq \Delta(G)$. We shall perform induction on $|E(G)|$. The case where $|E(G)| = 1$ is trivial. For $|E(G)| = m$, take any $xy \in E(G)$ and consider

$H := G - xy$. Note that $|E(H)| = m - 1$, so by the inductive hypothesis we have

$$\chi'(H) = \Delta(H) \leq \Delta(G).$$

Therefore, there exists a $\Delta(G)$ -edge-colouring on H . Notice that $d_H(x) \leq \Delta(G) - 1$ and $d_H(y) \leq \Delta(G) - 1$, but there are $\Delta(G)$ colours. Without loss of generality, assume that x is not incident to any α -edge and y is not incident to any β -edge. If x is not incident to any β -edge, we can colour xy with β in G and obtain a $\Delta(G)$ -edge-colouring in G . Otherwise, take a maximal α - β alternating path starting from x and ending at x' . Note that there is no α -edge between x and x' , so switching the α - and β -edges along the path retains the proper colouring in H . However, notice that now x is no longer incident to any β -edge in H , and so we can colour xy as β in G to obtain a proper $\Delta(G)$ -edge-colouring. \square

It turns out that for general graphs, we need at most one more colour to obtain a proper edge-colouring as compared to a bipartite graph.

Theorem 4.2.4 ► Vizing's Theorem

For every graph G , we have $\Delta(G) \leq \chi'(G) \leq \Delta(G) + 1$.

We can generalise Vizing's result to multigraphs.

Corollary 4.2.5 ► Vizing's Theorem for Multigraphs

For every loopless multigraph G , we have $\Delta(G) \leq \chi'(G) \leq \Delta(G) + \mu(G)$, where $\mu(G)$ is the greatest multiplicity of edges in G .

4.3 Perfect Graphs

In Proposition 4.1.4, we see that $\chi(G) \geq \omega(G)$. This motivates us to define a special type of graphs, the colouring of which is closely tied to the largest clique in them.

Definition 4.3.1 ► Perfect Graph

A graph G is **perfect** if for every induced subgraph $H \subseteq G$, we have $\chi(H) = \omega(H)$.

Clearly, K_n is a simple example for a perfect graph as every induced subgraph of K_n is also complete. Correspondingly, one can easily check that the empty graph $\overline{K_n}$ is also perfect. A non-empty bipartite graph G contains an edge as its maximum clique and so $\chi(G) = \omega(G) = 2$, which means G is also perfect. We can also prove that the complement of any bipartite graph must also be perfect.

Proposition 4.3.2 ▶ Complement of a Bipartite Graph Is Perfect

Let G be a bipartite graph, then \overline{G} is perfect.

Proof. Let $\overline{H} \subseteq \overline{G}$ be an induced subgraph, then $|V(\overline{H})|$ induces a subgraph $H \subseteq G$ which is the complement of \overline{H} . Note that every clique in \overline{H} is induced by an independent set of H , so $\omega(\overline{H}) = \alpha(H) = |V(H)| - \tau(H)$ by Proposition 2.2.3. Observe that $\chi(\overline{H})$ is the smallest number of independent sets to partition $V(\overline{H})$, but since H is bipartite, each of these independent sets induces either a clique, i.e., an edge, or an empty graph in H . Therefore, $\chi(\overline{H}) + \nu(H) = |V(H)|$. By Theorem 2.3.4, we have

$$\chi(\overline{H}) = |V(H)| - \nu(H) = |V(H)| - \tau(H) = \omega(\overline{H}),$$

and so \overline{G} is perfect. □

We can prove that the line graph of bipartite graphs are also perfect.

Proposition 4.3.3 ▶ Line Graphs of Bipartite Graphs Are Perfect

Let G be a bipartite graph, then $L(G)$ is perfect.

Proof. By Theorem 4.2.3, it suffices to prove that $\omega(L(G)) = \Delta(G)$. Let $H \subseteq L(G)$ be a clique, then H consists of edges of G which pair-wise share an incident vertex, so clearly $\omega(L(G)) = \Delta(G)$. □

There are many other families of perfect graphs, such as *comparability graphs* (undirected graph of a poset), *interval graphs* (intersection graph of intervals on the real line), *chordal graphs* (each cycle of length at least 4 has a chord), etc.

Perfect graphs have many nice properties, one of which is that given an n -vertex perfect graph, many graph parameters such as α , ω and χ can be computed with an $\mathcal{O}(n)$ algorithm.

Now, let us devise a way to characterise perfect graphs.

Theorem 4.3.4 ▶ Weak Perfect Graph Theorem

A graph is perfect if and only if its complement is perfect.

Proof. It suffices to prove that if G is perfect, then \overline{G} is perfect. We shall apply strong induction on $|V(G)|$. If $|V(G)| = 1$, then clearly both G and \overline{G} are perfect. Suppose that there is some integer $n > 1$ such that whenever $|V(G)| < n$, G being perfect implies that \overline{G} is perfect. Let $|V(G)| = n$ and take $\overline{H} \subseteq \overline{G}$ to be an induced subgraph. If $|V(\overline{H})| < n$, then by the inductive hypothesis \overline{H} is perfect, and so $\chi(\overline{H}) = \omega(\overline{H})$.

Otherwise, $\overline{H} = \overline{G}$, so it suffices to prove $\chi(\overline{G}) = \omega(\overline{G})$. Consider the following lemma:

Lemma 4.3.5 ▶ Vertex Expansion Preserves Perfectness

Let G be a perfect graph and define G' by

$$V(G') := V(G) \cup \{x'\}, \quad E(G') := E(G) \cup \{x'y : y \sim x\} \cup \{xx'\},$$

then G' is perfect.

Proof. We shall apply strong induction on $|V(G)|$. If $|V(G)| = 1$, then $G' \cong K_2$ which is perfect. Suppose that there exists $n > 1$ such that whenever $|V(G)| < n$, G' is perfect. Let $|V(G)| = n$ and $H \subseteq G'$ be an induced subgraph with $H \neq G'$. If at most one of x' and x is contained in H , then H is isomorphic to an induced subgraph in G . Otherwise, H can be obtained by extending x on some induced subgraph H' of G . Either case, by our inductive hypothesis we have $\omega(H) = \chi(H)$. Therefore, it suffices to prove that $\omega(G') \geq \chi(G')$.

Note that $\omega(G') \in \{\omega(G), \omega(G) + 1\}$, so we consider 2 cases. If $\omega(G') = \omega(G) + 1$, since G is perfect, we have $\omega(G') = \chi(G) + 1$, and so $\chi(G') \leq \chi(G) + 1 = \omega(G')$. Otherwise, $\omega(G') = \omega(G) = \chi(G)$. Fix a proper $\omega(G)$ -colouring on G and take any maximal clique $K \cong K_{\omega(G)}$ in G . Notice that $x \notin K$ because otherwise $V(K) \cup \{x'\}$ induces a clique of size $\omega(G) + 1$ in G' , which is not possible. Suppose $x \in U$ where U is some colour class in G , then clearly K contains some vertex in U . Therefore, $G - (U - \{x\})$ contains no $K_{\omega(G)}$. Since G is perfect,

$$\chi(G - (U - \{x\})) = \omega(G - (U - \{x\})) < \omega(G).$$

Note that in $U - \{x\}$, there is no vertex adjacent to x , and so $(U - \{x\}) \cup \{x'\}$ is an independent set in G' . Therefore, we can assign a new colour to $(U - \{x\}) \cup \{x'\}$. Together with an $(\omega(G) - 1)$ -colouring of $(G - (U - \{x\}))$, this gives an $\omega(G)$ -colouring in G' , and so

$$\omega(G') = \omega(G) \geq \chi(G').$$

□

Let \mathcal{K} be the family of cliques and \mathcal{A} be the family of maximal independent sets in G . We claim that there exists some $K \in \mathcal{K}$ such that $K \cap A \neq \emptyset$ for all $A \in \mathcal{A}$. Suppose on contrary that for every $K \in \mathcal{K}$, there is some $A_K \in \mathcal{A}$ such that $K \cap A_K = \emptyset$. For

every vertex $x \in V(G)$, define

$$k(x) := |\{K \in \mathcal{K} : x \in A_K\}|.$$

Let $G_x \cong K_{k(x)}$ be a clique. We construct a graph G' by

$$\begin{aligned} V(G') &:= \{G_x : x \in V(G)\}, \\ E(G') &:= \bigcup_{xy \in E(G)} (V(G_x) \times V(G_y)), \end{aligned}$$

i.e., $V(G_x) \cup V(G_y)$ induces a clique in G' if and only if $x \sim y$ in G . Notice that every $G_x \subseteq G'$ corresponds to some unique $x \in V(G)$, so we can construct G' by repeatedly expanding on vertices of G . Since G is perfect, by Lemma 4.3.5 we know that G' is perfect and so $\chi(G') \leq \omega(G')$. Notice that if $\bigcup_{i=1}^m V(G_{x_i})$ induces a maximal clique K' in G' , then $\{x_1, x_2, \dots, x_m\}$ must also induce a maximal clique $X \in \mathcal{K}$ in G . Note that

$$\begin{aligned} |V(K')| &= \sum_{x \in V(X)} k(x) \\ &= \sum_{x \in V(X)} |\{K \in \mathcal{K} : x \in A_K\}| \\ &= \sum_{K \in \mathcal{K}} |X \cap A_K| \end{aligned}$$

Since X is a clique, $|X \cap A_K| \leq 1$. Notice that there exists $A_X \in \mathcal{A}$ with $X \cap A_X = \emptyset$, so $\omega(G') = |V(K')| \leq |\mathcal{K}| - 1$. However,

$$\begin{aligned} |V(G')| &= \sum_{x \in V(G)} k(x) \\ &= \sum_{K \in \mathcal{K}} |A_K| \\ &= \alpha(G)|\mathcal{K}|. \end{aligned}$$

Take any independent set $A \subseteq V(G')$, then for any $a, b \in A$, a, b are in different cliques. Suppose $a \in G_x$ and $b \in G_y$, then $xy \notin E(G)$ because otherwise $V(G_x) \cup V(G_y)$ induces a clique in G' , which is not possible. Therefore, there exists an independent set in G which has the same size as A , and so $\alpha(G') \leq \alpha(G)$. Therefore,

$$\chi(G') \geq \frac{|V(G')|}{\alpha(G')} \geq \frac{\alpha(G)|\mathcal{K}|}{\alpha(G)} = |\mathcal{K}|,$$

which is a contradiction. Therefore, we can take some $K \in \mathcal{K}$ such that $K \cap A \neq \emptyset$

for all $A \in \mathcal{A}$, and so

$$\omega(\overline{G} - K) = \alpha(G - K) < \alpha(G) = \omega(\overline{G}).$$

By the inductive hypothesis, $\overline{G} - K$ is perfect, and so $\chi(\overline{G} - K) = \omega(\overline{G} - K)$. Fixing a $\chi(\overline{G} - K)$ -colouring in $\overline{G} - K$ and colouring $V(K)$ with a new colour yields a proper colouring in \overline{G} because $V(K)$ is an independent set in \overline{G} . Therefore,

$$\begin{aligned}\chi(\overline{G}) &\leq \chi(\overline{G} - K) + 1 \\ &= \omega(\overline{G} - K) + 1 \\ &\leq \omega(\overline{G}).\end{aligned}$$

□

There is a stronger characterisation of perfect graphs, which has remained an unsolved conjecture until 2006. We first define the following structure:

Definition 4.3.6 ► Odd Hole

An induced odd cycle of length at least 5 is called an **odd hole** in a graph. The complement of an odd hole is said to be an **odd anti-hole**.

The characterisation states the following:

Theorem 4.3.7 ► Strong Perfect Graph Theorem

A graph G is perfect if and only if it contains no odd hole or odd anti-hole.

Planarity

5.1 Planar Graph

Four-Colour Problem is a famous problem in graph theory, which states that **any map drawn on a plane can be coloured with 4 distinct colours such that no neighbouring regions share the same colour**. It is clear that we can model such a map by taking every enclosed region as a vertex and join any vertices whose corresponding regions share a border. Intuitively, in such a graph, the edges never cross each other.

Definition 5.1.1 ► Planar Graph

A **planar graph** is a graph which can be embedded in a plane such that its edges only intersect at end points. Given a planar representation of a graph G , an intersection between edges of G which is not an end point is known as a **crossing**.

An intuition here is that if a graph contains many edges, i.e., its edges are dense, then it is more difficult to avoid crossings. We will state the following simple proposition first:

Proposition 5.1.2 ► K_5 and $K_{3,3}$ Are not Planar

K_5 and $K_{3,3}$ are not planar graphs.

Clearly, any plane drawing of any graph is isomorphic to the graph itself. To distinguish between a “planar graph” and a “planar drawing of a graph”, we introduce the following definition:

Definition 5.1.3 ► Plane Graph

A **plane graph** is a valid plane drawing of a planar graph G , such that there exists some disc $D \subseteq \mathbb{R}^2$ with $G \subseteq D$. For any space S enclosed by the edges of G , we say that S is an **outer face** if $S \subseteq D$ and an **inner face** otherwise.

Euler once developed a formula that handles the relationship between the numbers of faces, edges and vertices of a plane graph.

Theorem 5.1.4 ► Euler's Formula

Let G be a connected plane graph with n vertices, m edges and ℓ faces, then

$$n - m + \ell = 2.$$

Proof. For every $n \in \mathbb{Z}^+$, we shall apply induction on m . Note that $m \geq n - 1$ for G to be connected. If $m = n - 1$, then G is a tree and $\ell = 1$, so

$$n - m + \ell = n - (n - 1) + 1 = 2.$$

For $m \geq n$, G must contain some cycle. Take a cycle $C \subseteq G$, then for any $e \in E(C)$, e lies on the boundary between exactly 2 faces. Therefore, $G' := G - e$ is a connected plane graph with n vertices, $(m - 1)$ edges and $(\ell - 1)$ faces, and by the inductive hypothesis we have

$$n - (m - 1) + (\ell - 1) = n - m + \ell = 2.$$

□

An immediate corollary of Theorem 5.1.4 allows us to determine the number of edges in certain planar graphs.

Corollary 5.1.5 ► Number of Edges in a Planar Graph

Any planar graph G with order at least 3 contains at most $(3v(G) - 6)$ edges.

Proof. It suffices to prove for the case where G is connected. If G has only one face, then G must be a tree, and so

$$e(G) = v(G) - 1 \leq 3v(G) - 6.$$

Otherwise, every face of G is bounded by at least 3 edges. Let G contain m' edges which are not part of any cycle, then any of these m' edges lies on the boundary of the outer face only. Suppose G contains ℓ faces, then every face contains at least 3 edges, each of which must be part of some cycle. Let e_i be the number of edges forming the boundary of the i -th face and are part of some cycle, then

$$m = m' + \frac{\sum_{i=1}^{\ell} e_i}{2} \geq m' + \frac{3\ell}{2}.$$

By Theorem 5.1.4,

$$2 = v(G) - m + \ell \leq v(G) - m + \frac{2}{3}(m - m') = v(G) - \frac{1}{3}m - \frac{2}{3}m'.$$

Therefore, $m \leq 3\left(v(G) - \frac{2}{3}m' - 2\right) \leq 3v(G) - 6$. \square

Remark. In fact, we can further prove that every maximal planar graph G , i.e., $G + uv$ for any $u, v \in V(G)$ is not planar, with $v(G) \geq 3$ must have a plane drawing which is a triangulation, i.e., every face is a triangle, and so $e(G) = 3v(G) - 6$.

Note that in the formal definition, we only require that the plane drawing of a planar graph uses curves to represent each edge. However, it turns out that using straight lines already suffices.

Theorem 5.1.6 ▶ Fáry's Theorem

Any planar graph G can be draw with straight edges in a plane.

Proof. It suffices to prove for the case where G is maximally planar, i.e., $e(G) = 3v(G) - 6$. We shall apply induction on $v(G)$. The case where $v(G) = 3$ is trivial. Suppose that there exists some integer $k \geq 3$ such that any k -vertex maximally planar graph has a straight-line plane drawing. Let G be a $(k+1)$ -vertex maximally planar graph and let A, B, C be the vertices on the boundary of the outer face of G . We claim that there exists some $v \in V(G) - \{A, B, C\}$ such that $d_G(v) \leq 5$, because otherwise

$$2e(G) > \sum_{v \in V(G)} 6(k+1-3) + 3 \times 2 = 6(k+1) - 12,$$

which is not possible. Consider $G' := G - v$, then G' is isomorphic to some subgraph of a k -vertex maximally planar graph, and so by the inductive hypothesis we can embed G' in a plane with straight edges. Consider the face in G' which contains v in G . Notice that this face is a polygon P with at most 5 edges. Since v is in the interior of P , $P + v$ is a 6-vertex planar graph. One may check that v can be joined to the vertices of P using only straight lines, and so G can be embedded in a plane with only straight edges. \square

For non-planar graphs, we may still wish to embed them into a plane using the most optimal drawing possible.

Definition 5.1.7 ▶ Crossing Number

For any graph G , the **crossing number** of G is the minimum number of crossings between edges to embed G into a plane.

Now, we make an attempt to characterise the structure of planar graphs. We first introduce 2 important definitions.

Definition 5.1.8 ▶ Subdivision

A **subdivision** of a graph G is obtained by replace the edges of G with internally vertex-disjoint paths of length at least 2.

Definition 5.1.9 ▶ Topological Minor

A graph H is called a **topological minor** of a graph G if G contains a subgraph which is isomorphic to a subdivision of H .

In Proposition 5.1.2, we state that K_5 and $K_{3,3}$ are non-planar. Now we will see how this fact can be used to determine the planarity of general graphs.

Proposition 5.1.10 ▶ Sufficient Condition for Non-planarity

A graph G is not planar if it contains a subgraph which is a subdivision of K_5 or $K_{3,3}$.

Proof. It suffices to show that any subdivision of K_5 and $K_{3,3}$ are non-planar. Suppose on contrary that there exists some subdivision H of K_5 which is planar. Note that for any $u_1u_2, v_1v_2 \in E(K_5)$, the corresponding u_1-u_2 path and v_1-v_2 path in H are internally vertex-disjoint. Therefore, replacing these 2 paths in a plane drawing of H with singleton edges does not produce crossing edges. Apply this replacement repeatedly and we will eventually obtain a plane drawing of K_5 , which is a contradiction. Similarly, we can also prove the any subdivision of $K_{3,3}$ cannot be planar. \square

In fact, we can extend the above proposition to a sufficient and necessary condition for planarity. However, before we prove the theory properly, let us first examine a few preliminary results.

Definition 5.1.11 ▶ Minor

A graph H is called a **minor** of a graph G if it can be obtained by deleting edges, deleting vertices or contracting edges from G .

Intuitively, minor is a transitive relation. Note that any subgraph of G must be a minor of G , but the converse is not true. One can also easily check that any topological minor of G

must also be a minor of G (and so the name “topological minor”).

Proposition 5.1.12 ▶ Topological Minor Is a Minor

If H is a topological minor of G , then H is a minor of G .

Proof. By Definition 5.1.9, G contains a subdivision of H . Denote this subdivision as K , then it is clear that we can obtain H by contracting the edges of K repeatedly until we restore $E(H)$. Therefore, H is a minor of K and so it must be a minor of H . \square

Note that the converse of the above proposition is not true in general. However, we can impose an additional restriction to make the converse work.

Proposition 5.1.13 ▶ A Minor Can Be a Topological Minor

Every minor H of G with $\Delta(H) \geq 3$ is a topological minor of G .

Additionally, we can view a minor in terms of *branching sets*.

Definition 5.1.14 ▶ Branching Set

Let G be a graph. A partition $\mathcal{V} := \{V_1, V_2, \dots, V_n\}$ is called **branching sets** of G if for every $V_x \in \mathcal{V}$,

1. $x \in V(G)$,
2. $G[V_x]$ is connected, and
3. there exists some $V_y \in \mathcal{V} - \{V_x\}$ such that there exists at least one edge $uv \in E(G)$ with $u \in V_x$ and $v \in V_y$.

It is clear that if we contract all edges in a branching set, the set will be reduce to a vertex in some minor of G .

We use the notation “ G is MH ” to indicate that G contains H as a minor, and “ G is TH ” to indicate that G contains H as a topological minor.

We shall consider the following theorem which is important for deriving a characterisation for planar graphs:

Theorem 5.1.15 ▶ Wagner’s Theorem

A graph is planar if and only if it contains neither K_5 nor $K_{3,3}$ as a minor.

Proof. By Proposition 5.1.2, it suffices to prove sufficiency. We first consider 3-connected graphs.

Lemma 5.1.16 ▶ Characterisation of 3-connected Planar Graphs

If a 3-connected graph G contains neither K_5 nor $K_{3,3}$ as a minor, then G is planar.

Proof. We shall apply induction on $|V(G)|$. For $|V(G)| = 1$, it is trivial that G is planar. Suppose that there exists some $k \in \mathbb{Z}^+$ such that any graph of order k containing neither K_5 nor $K_{3,3}$ as a minor is planar. Let G be a 3-connected graph with $|V(G)| = k + 1$. By Theorem 3.3.8, there exists some $xy \in E(G)$ such that $d_G(x), d_G(y) \geq 3$ and $G' := G/xy$ is 3-connected. Clearly, G' does not contain either K_5 or $K_{3,3}$ as a minor, so by the inductive hypothesis, G' is planar. Fix a plane drawing \tilde{G} of G' . Suppose xy is contracted to $v_{xy} \in G'$ and let F be a face in $\tilde{G} - v_{xy}$ such that $v_{xy} \in F$. Consider $X := N_G(x) - \{y\}$ and $Y := N_G(y) - \{x\}$, then clearly $X \cup Y$ is contained by the boundary of F , because otherwise there will be crossings in \tilde{G} . This means \tilde{G} is a plane drawing of $G - y$ by replacing v_{xy} with x .

Since \tilde{G} is 3-connected, $\tilde{G} - v_{xy}$ must be 2-connected. We claim that the boundary of F , denoted as C , must be a cycle, because otherwise $\tilde{G} - v_{xy}$ is a tree and cannot be 2-connected. Re-label $X \cap V(C) = \{x_1, x_2, \dots, x_n\}$ such that the x_i 's are placed in clockwise order. Define P_i to be the clockwise x_i - x_{i+1} path in C (for simplicity, we define $x_{n+1} = x_1$). We consider 2 cases.

If $Y \subseteq X$, we claim that $|Y| \leq 2$. Suppose on contrary that $|Y| \geq 3$, then any 3 vertices from Y together with x and y induces a subdivision of K_5 in G , which is a contradiction. However, recall that $d_G(y) \geq 3$, so $|Y| \geq 2$ and so $|Y| = 2$. Let $Y = \{x_m, x_\ell\}$ with $\ell > m$. If there is some $x_1 \in V(P_m)$ and $x_2 \in V(C) - V(P_m)$, then we can find a subdivision of $K_{3,3}$ with partite sets $\{y, x_1, x_2\}$ and $\{x, x_m, x_\ell\}$, which is not possible. Therefore, x_m and x_ℓ are consecutive, which means that we can simply place y in the face containing x , x_m and x_ℓ .

Otherwise, there is some $y_1 \in V(P_i) - \{x_i, x_{i+1}\}$ for some P_i . We claim that $Y \subseteq V(P_i)$. Suppose on contrary that there is some $y_2 \in Y - V(P_i)$, then one may check that there is a subdivision of $K_{3,3}$ on $\{y, x_i, x_{i+1}\}$ and $\{x, y_1, y_2\}$, which is a contradiction. Therefore, we can place y in the face containing x , x_i and x_{i+1} . Therefore, G is planar. \square

Let G be a graph that is neither MK_5 nor $MK_{3,3}$. If G is 3-connected, then by Lemma 5.1.16 we are done. Otherwise, suppose on contrary that G is non-planar. Note that G

must not be TK_5 nor $TK_{3,3}$. Without loss of generality, we can take G as the smallest non-planar graph with said property. By minimality of G , it must be connected, because otherwise any connected component of G is a smaller non-planar graph which is neither TK_5 nor $TK_{3,3}$. We claim that G does not have a cut vertex. Suppose on contrary that $x \in V(G)$ is a cut vertex. Take H to be a connected component of G and define $H_1 := G[V(H) \cup \{x\}]$ and $H_2 := G - H$. Notice that both H_1 and H_2 are planar because neither is either TK_5 or $TK_{3,3}$, and so we can find their respective plane drawings such that x is on the outer face. By identifying x , we obtain a plane drawing of G , which is not possible. Therefore, $\kappa(G) = 2$.

Take $\{x, y\}$ to be a vertex cut of G . Let H be a connected component in $G - \{x, y\}$ and let $V_1 := V(H) \cup \{x, y\}$, $V_2 := V(G) - V(H)$. Notice that both $G[V_1]$ and $G[V_2]$ are planar, and so we claim that $xy \notin E(G)$ because otherwise we can find the plane drawings for $G[V_1]$ and $G[V_2]$ respectively such that xy is in the outer face in both drawings, from which we can construct a plane drawing for G .

Define $G_i := G[V_i] + xy$ for $i = 1, 2$. If both G_1 and G_2 are planar, by repeating the previous argument we obtain a contradiction. Without loss of generality, assume that G_1 is not planar, then by the minimality of G we know that G_1 is either TK_5 or $TK_{3,3}$. Let $S \subseteq G_1$ be a subdivision of either K_5 or $K_{3,3}$, then S must contain the edge xy because otherwise $S \subseteq G$, which is not possible. However, notice that there exists a vertex $v \in V_2$ such that $v \in N_G(x) \cap N_G(y)$ because otherwise $\{x, y\}$ is not a minimum vertex cut. Let P_2 be the path induced by $\{x, y, v\}$, then $(S - xy) \cup P_2$ is a subdivision of either K_5 or $K_{3,3}$ in G , which is a contradiction. Therefore, G must be planar. \square

Clearly, if a graph is not TK_5 nor $TK_{3,3}$, we can immediately use Theorem 5.1.15 to prove that it is planar. With the above results, we can easily prove *Kuratowski's Theorem*.

Theorem 5.1.17 ► Kuratowski's Theorem

A graph is planar if and only if it contains no subdivision of K_5 or $K_{3,3}$.

There is also an equivalent definition for planar graphs. However, we shall state the theorem without proof as the proof is highly non-trivial.

Theorem 5.1.18 ► Hanani-Tutte Theorem

A graph is planar if and only if it has a drawing in which every pair of disjoint edges crosses an even number of times.

5.2 Dual Graph

Recall the Four-Colour Problem. In modelling the problem as a graph, we can either take each country as a vertex and define bordering using edges. Equivalently, we could have used edges to represent each border first and define vertices as the intersection of borders, where the countries become faces in a planar graph. This motivates us to define the notion of *dual graphs*. We start with a definition that is easier to visualise.

Definition 5.2.1 ► Geometric Dual

Let G be a planar graph with plane drawing \tilde{G} . Let $\mathcal{F}(G)$ be the family of faces in \tilde{G} . The **geometric dual** of G is a graph G^* such that $V(G^*) := \mathcal{F}(G)$ and every $e^* \in E(G^*)$ is induced by an edge $e \in E(G)$ on the boundary between 2 faces.

Note that in the above definition, even for a simple planar graph G , its dual G^* might be a multi-graph because there could be faces in G whose boundary consists of multiple edges. Intuitively, the dual of a planar graph is always planar and

$$|V(G^*)| = |\mathcal{F}(G)|, \quad |E(G^*)| = |E(G)|, \quad |\mathcal{F}(G^*)| = |V(G)|.$$

The above identities can be proved by applying Theorem 5.1.4. One may also verify that $G^{**} \cong G$, which also aligns with our intuition. Correspondingly, we have the following proposition:

Proposition 5.2.2 ► Cycles Induce Edge Cuts in the Dual

Let G be a connected plane multi-graph. For any $S \subseteq E(G)$, S induces a cycle in G if and only if $S^* := \{e^* : e \in S\}$ is a minimal edge cut in G^* .

Proof. Suppose that S induces a cycle in G . For every $e \in S$, let I_e and O_e be the faces in the interior and exterior of the cycle respectively with e on their boundary. Clearly, for every $I_e \in V(G^* - S^*)$, I_e is not adjacent to any face in the exterior of the cycle. Therefore, S^* is an edge cut. Clearly, S^* is minimal because removing any fewer number of edges cause some $I_e O_e$ to remain in the resultant graph, but all interior faces to the cycle induces a connected graph in G^* .

Suppose conversely that S^* is a minimal edge cut in G^* , then $G^* - S^*$ contains exactly 2 connected components. Let the connected components be H_1 and H_2 , then $V(H_1)$ and $V(H_2)$ form a bipartition of $\mathcal{F}(G)$. Clearly, the boundary between $V(H_1)$ and $V(H_2)$ in G must contain a cycle, and by minimality of S^* , this boundary is the cycle itself. \square

Proposition 5.2.2 motivates us to define the notion of an *abstract dual* without knowing first an explicit drawing of the planar graph.

Definition 5.2.3 ► Abstract Dual

Let G be a multigraph. A graph G^* is said to be an **abstract dual** of G if there exists a bijection $f : E(G) \rightarrow E(G^*)$ such that for every $S \subseteq E(G)$, S induces a cycle in G if and only if $S^* := f(S)$ is a minimal edge cut in G^* .

With a smart guess, we are able to align our intuition with the following characterisation, which also answers the question about the existence of abstract dual for each graph:

Theorem 5.2.4 ► Whitney's Abstract Dual Theorem

A graph is planar if and only if it has an abstract dual.

5.3 Four Colour Theorem

Now to answer the Four-Colour Problem posed at the beginning of the chapter, we start with a much weaker result.

Theorem 5.3.1 ► Six Colour Theorem

For every planar graph G , $\chi(G) \leq 6$.

Proof. The case where $v(G) \leq 2$ is trivial. If $v(G) \geq 3$, by Corollary 5.1.5, we have $e(G) \leq 3v(G) - 6$. This immediately implies that

$$\delta(G) \leq \frac{2e(G)}{v(G)} \leq 6 - \frac{12}{v(G)} < 6.$$

For any planar graph G , we can find a $\chi(G)$ -critical subgraph $H \subseteq G$. By Proposition 4.1.8, $\delta(H) \geq \chi(G) - 1$. However, $\delta(H) \leq \delta(G) \leq 5$, so $\chi(G) - 1 \leq 5$, which implies that $\chi(G) \leq 6$. □

We can improve this proof to reduce the upper bound to 5.

Theorem 5.3.2 ► Five Colour Theorem

For every planar graph G , $\chi(G) \leq 5$.

Proof. We shall apply induction on $v(G)$. The case where $v(G) = 1$ is trivial. Suppose that there exists some $k \in \mathbb{Z}^+$ such that any planar graph of degree k is 5-colourable, consider G to be a planar graph of degree $k + 1$. Note that we can take some $v \in V(G)$

with $d_G(v) \leq 5$ since $\delta(G) \leq 5$. Define $G' := G - v$ and by the inductive hypothesis, we can fix a proper 5-colouring on G' . If $d_G(v) \leq 4$, then we are done. Otherwise, $d_G(v) = 5$ and denote $N_G(v) := \{v_1, v_2, v_3, v_4, v_5\}$ in clockwise order. If any two vertices in $N_G(v)$ share the same colour, we are done. Otherwise, suppose v_i is in colour i for $i = 1, 2, 3, 4, 5$. Let $G_{i,j}$ be the subgraph of G' induced by colour classes associated to i and j . If there is a v_1 - v_3 path in $G_{1,3}$ and a v_2 - v_4 path in $G_{2,4}$, we claim that these two paths must intersect at some vertex, because otherwise there is some edge in one of the path which either crosses with some edge in the other path or one of $\{vv_1, vv_2, vv_3, vv_4, vv_5\}$. However, this implies that there exists one vertex which is in two distinct colour classes, which is not possible. Therefore, without loss of generality, assume that v_1 and v_3 are in different connected components in $G_{1,3}$. This means we can switch the colours 1 and 3 in the connected component of $G_{1,3}$ containing v_1 and colour v in 1 to obtain a proper 5-colouring of G , which implies that $\chi(G) \leq 5$. \square

However, note that we cannot easily replicate the proof for Theorem ?? to the 4-colour case because we may not be able to find a vertex of degree at most 4.

Theorem 5.3.3 ► Four Colour Theorem

For every planar graph G , $\chi(G) \leq 4$.

If the graph has some additional special properties, we can further improve the bound.

Theorem 5.3.4 ► Grötzsch's Theorem

Every triangle-free planar graph is 3-colourable.

Hamiltonian Graph

6.1 Eulerian Graph

A classic problem regarding graph traversal in connected graphs is the Königsberg Bridge Problem:

Let A, B, C, D be 4 distinct vertices such that there are 2 edges between A and B , 2 edges between A and C , and 1 edge between A and D , B and D , C and D . Can all the edges be visited exactly once in a single traversal of the graph produced?

This can be generalised as: given a connected multigraph G , does there exist a circuit in G which contains all the edges of G ? Such multigraphs are said to be *Eulerian*.

Definition 6.1.1 ► Eulerian Circuit

Let G be a connected multigraph, an **Eulerian circuit** in G is a circuit which uses all edges of G exactly once.

Intuitively, if a graph is Eulerian, then following any Eulerian circuit will visit each of its vertices for an even number of times as there are equally many incoming edges as outgoing edges for every vertex in a circuit. This implies that an Eulerian graph will necessarily force all of its vertices to have even degrees. However, it turns out that actually this is also a sufficient condition for the existence of Eulerian circuits!

Theorem 6.1.2 ► Necessary and Sufficient Condition for Eulerian Graphs

A connected multigraph G is Eulerian if and only if every vertex in G has an even degree.

Proof. The necessity is trivial, so we will only prove for sufficiency.

Consider the case where $e(G) = 0$, then the only connected multigraph is the trivial graph consisting of a singleton vertex, which is Eulerian.

Suppose that for all $k < m$ where $m \in \mathbb{Z}^+$, a connected multigraph H with $e(H) = k$ is Eulerian if every vertex in H has an even degree. Let G be a connected multigraph with $e(G) = m > 0$ such that every vertex in G has an even degree, then $\delta(G) \geq 2$. By Proposition 1.2.6, there exists a cycle $S \subseteq G$ where $e(S) \geq 3$.

Let G' be the multigraph such that $V(G') = V(G)$ and $E(G') = E(G) - E(S)$, then clearly, $e(G') < m$ and every vertex in G' has an even degree. Therefore, each connected component of G' is Eulerian.

Let C_1 be a connected component of G' and let $v_1 \in V(C_1) \cap V(S)$. Note that there exists an Eulerian circuit in C_1 which starts and ends with v_1 . We can traverse along this circuit and then traverse in the clockwise orientation along S until we reach another vertex in S which is in some connected component of G' and repeat the process. Note that $v_1 \in V(S)$, so we will eventually traverse back to v_1 , which gives an Eulerian circuit in G . \square

Intuitively, even if a graph G is not Eulerian, it is possible to traverse all edges in G with finitely many trails. This is known as a decomposition of G into trails.

Proposition 6.1.3 ► Minimal Number of Trails to Decompose A Multigraph

Let G be a graph with $2k$ vertices having odd degrees for some $k \in \mathbb{N}$, then the minimal number of trails needed to decompose G is $\max\{k, 1\}$.

Proof. The case where $k = 0$ is immediate by Theorem 6.1.2. For $k \geq 1$, suppose on contrary that G can be decomposed with $k - 1$ trails labelled as T_1, T_2, \dots, T_{k-1} . Since a trail contains at most 2 vertices with odd degrees, then

$$\left| \left\{ v \in \bigcup_{i=1}^{k-1} T_i : d_G(v) \text{ is odd} \right\} \right| \leq 2(k-1) < 2k,$$

which is a contradiction. Therefore, we need at least k trails to decompose G .

Let v_1, v_2, \dots, v_{2k} be the vertices in G with odd degrees. Let G' be the graph produced by adding the edges $v_1v_2, v_3v_4, \dots, v_{2k-1}v_{2k}$ to G , then the vertices in G' all have even degrees. Therefore, there exists an Eulerian circuit in G' by Theorem 6.1.2.

Note that for all $i = 1, 2, \dots, k - 1$, $v_{2i-1}v_{2i}$ and $v_{2i+1}v_{2i+2}$ are disjoint, so there exists a $v_{2i}-v_{2i+1}$ trail. Note also that there exists a $v_{2k}-v_1$ trail. The union of these trails is exactly $G' - v_1v_2 - v_3v_4 - \dots - v_{2k-1}v_{2k} = G$. \square

6.2 Hamiltonian Graph

Recall that in Definition 6.1.1, we define a way to traverse a graph without using repeated edges. Now, we would like to further strengthen this notion, i.e., we would like to know whether we can traverse a graph by visiting each vertex exactly once.

Definition 6.2.1 ► Hamiltonian Graph

A graph G is **Hamiltonian** if it contains a cycle which uses every vertex in G . Such a cycle is known as a **Hamiltonian cycle**. A path containing every vertex in a graph is called a **Hamiltonian path**.

Clearly, K_n and $K_{m,n}$ are Hamiltonian. We can also verify that tetrahedral graph, octahedral graph, cubical graph, icosahedral graph and dodecahedral graph are all Hamiltonian. In fact, the hypercube graph can be easily proven to be Hamiltonian.

Proposition 6.2.2 ► Hypercube Is Hamiltonian

The n -dimensional hypercube graph Q^n is Hamiltonian.

Proof. We shall apply induction on n . The case where $n = 1$ is trivial. For any integer $n > 1$, Q^n consists of 2 identical copies of Q^{n-1} plus a perfect matching between their vertex sets. Fix 2 Hamiltonian cycles $v_1v_2 \cdots v_{2^{n-1}}$ and $u_1u_2 \cdots u_{2^{n-1}}$ in the 2 copies of Q^{n-1} respectively. Then clearly, $v_1v_2 \cdots v_{2^{n-1}}u_{2^{n-1}-1} \cdots u_1$ is a Hamiltonian cycle in Q^n . \square

As with many other graph properties, the Petersen graph is yet again a counter example for Hamiltonian graphs.

Proposition 6.2.3 ► The Petersen Graph Is not Hamiltonian

The Petersen graph P is not Hamiltonian.

Proof. Suppose on contrary that there is a Hamiltonian cycle $C_{10} \subseteq P$, then there are 5 edges in P which are not in C_{10} . We claim that at least one of these edges do not join vertices at distance 5 apart along C_{10} , because otherwise we can find a $C_4 \subseteq P$, which is not possible because the girth of P is 5. Similarly, there is no edge joining vertices at distance at most 3 apart along C_{10} . Therefore, there exists at least one edge $uv \in E(P) - E(C_{10})$ such that $d_{C_{10}}(u, v) = 4$. Let u' be a vertex at distance 5 away from v in C_{10} , then there is no edge incident to u' , which is a contradiction. \square

In fact, the Petersen graph is the smallest *hypo-Hamiltonian* graph.

Definition 6.2.4 ▶ Hypo-Hamiltonian Graph

A graph G is **hypo-Hamiltonian** if G is not Hamiltonian but $G - v$ is Hamiltonian for any $v \in V(G)$.

Now let us find some useful conditions to determine a graph as non-Hamiltonian.

Proposition 6.2.5 ▶ Easy Necessary Condition for Hamiltonian Graphs

For any n -vertex Hamiltonian graph G , the number of connected components in $G - X$ for any $X \subseteq V(G)$ is at most $|X|$.

Proof. Let $C_n \subseteq G$ be a Hamiltonian cycle. Note that $\kappa(G) \geq \kappa(C_n)$, so it suffices to prove the statement for C_n . Note that $C_n - v$ for any $v \in V(C_n)$ has 1 connected component, and every time we remove one more vertex, the number of connected components increases by at most 1. Therefore, for any $X \subseteq V(C_n)$, the number of connected components in $C_n - X$ is at most $|X|$. \square

Therefore, if there is some $X \subseteq V(G)$ such that the number of connected components in $G - X$ is more than $|X|$, then we can conclude that G is not Hamiltonian.

Remark. This condition is not necessary for non-Hamiltonicity. For example, the Petersen graph G_P is not Hamiltonian but $G_P - X$ has at most $|X|$ connected components for every $X \subseteq V(G_P)$.

So far, there has not been any good characterisation for Hamiltonian graphs. However, we can still obtain some sufficient conditions for a graph to be Hamiltonian.

First, note that having a lot of edges does not guarantee Hamiltonicity (consider the graph $K_{n-1} \cup K_1$). Locally, it is easy to see that $\delta(G) \geq 2$ must be satisfied for G to be Hamiltonian, but our counter example demonstrates that we need the graph to be very close to a complete graph to guarantee this.

Intuitively, we might wish to propose a lower bound for $\delta(G)$ such that when $\delta(G)$ is large enough, Hamiltonicity is guaranteed. Clearly, we need the graph to first be connected. However, notice that if we take a disjoint union of 2 K_n 's, then $\delta(G) = n - 1$ but the graph is not even connected. In fact, we can have an even higher minimum degree without a Hamiltonian cycle. Consider complete bipartite graphs $K_{n-1, n+1}$ and $K_{m, m+1}$. Clearly, there is no Hamiltonian cycle but the minimum degrees are $n - 1$ and m respectively.

However, by an argument using Pigeonhole Principle, one can easily see that it is impossible to avoid a Hamiltonian cycle if any vertex is incident to at least half of the vertices.

Theorem 6.2.6 ▶ Dirac's Theorem

Every graph G with at least 3 vertices and $\delta(G) \geq \frac{n}{2}$ has a Hamiltonian cycle.

Proof. First, notice that G must be connected because otherwise any vertex in the smallest connected component of G has at most $\left(\frac{n}{2} - 1\right)$ neighbours. Let

$$P := v_0 v_1 \cdots v_k$$

be the longest path in G . Note that $N_G(v_k), N_G(v_0) \subseteq V(P)$, so at least $\frac{n}{2}$ integers $i \in \{0, 1, 2, \dots, k-1\}$ satisfy $v_i \sim v_k$ and at least $\frac{n}{2}$ integers $i \in \{0, 1, 2, \dots, k-1\}$ satisfy $v_{i+1} \sim v_0$. However, $k \leq n-1$, so by Pigeonhole Principle, there exists some $i \in \{0, 1, 2, \dots, k-1\}$ such that $v_i \sim v_k$ and $v_{i+1} \sim v_0$. Consider the cycle $C := v_0 v_{i+1} v_{i+2} \cdots v_k v_i v_{i-1} \cdots v_1$. We claim that this cycle must be Hamiltonian, because otherwise there exists some $u \in V(G) - V(C)$ such that $u \sim v_i$ for some $v_i \in V(C)$, which gives us a path in G longer than P . This is a contradiction. \square

An easy corollary of Dirac's Theorem states the following result on the length of paths in a Hamiltonian graph:

Corollary 6.2.7 ▶ Length of Paths in Hamiltonian Graphs

Every n -vertex Hamiltonian graph contains a path of length at least $\min\{n-1, 2\delta(G)\}$.

The proof of the corollary is trivial and is left to the reader as an exercise. An immediate result of the corollary states the following:

Corollary 6.2.8 ▶ Upper Bound of the Size of a Graph Using Path Length

If G is an n -vertex graph without any path of length k , where $k \in \mathbb{Z}^+$, then

$$e(G) \leq \frac{k-1}{2}n.$$

Proof. We shall apply induction on n . The case where $n \leq k$ is trivial because

$$e(G) \leq \binom{n}{2} \leq \frac{n(k-1)}{2}.$$

Suppose there is some integer $m \geq k$ such that all P_k -free graph with m vertices have at most $\frac{k-1}{2}m$ edges. Let G be an $(m+1)$ -vertex graph. Without loss of generality, assume that G is connected, otherwise we apply the same argument to each connected

component of G . Take $v \in V(G)$ with $d_G(v) = \delta(G)$. We claim that $\delta(G) < \frac{k}{2}$ because otherwise by Corollary 6.2.7, we can find a $P_k \subseteq G$. This means that $d_G(v) \leq \frac{k-1}{2}$. Define $G' := G - v$, then by the inductive hypothesis,

$$e(G') \leq \frac{(k-1)}{2}(n-1),$$

and so

$$e(G) \leq e(G') + \frac{k-1}{2} = \frac{(k-1)}{2}n.$$

□

We can generalise Theorem 6.2.6 into the following:

Theorem 6.2.9 ► Ore's Theorem

A graph G on at least 3 vertices is Hamiltonian if for all $u, v \in V(G)$ with $u \not\sim v$, we have $d_G(u) + d_G(v) \geq n$.

We first prove that G is connected. Suppose on contrary that G is not connected. Let H be the smallest connected component in G , then $|V(H)| \leq \frac{n}{2}$. Notice that H must be a clique, because otherwise there exist $u_1, u_2 \in V(H)$ with $u_1 \not\sim u_2$ and

$$d_G(u_1) + d_G(u_2) = d_H(u_1) + d_H(u_2) < n,$$

which is not possible. We claim that Take any vertex $u \in V(H)$ and for any $u' \in V(G) - V(H)$, we have

$$d_G(u) + d_G(u') \leq |V(H)| - 1 + (n - |V(H)| - 1) < n,$$

which is a contradiction. We shall prove G contains a Hamiltonian cycle by contradiction. Suppose on contrary that G contains no Hamiltonian cycle. Without loss of generality, let G be an edge-maximal non-Hamiltonian graph such that $d_G(u) + d_G(v) \geq n$ for any non-adjacent $u, v \in V(G)$. We claim that G must contain a Hamiltonian path, because otherwise we can continue adding edges to join new vertices to the longest path in G without violating the condition on the sum of degrees. Let $P := v_1 v_2 \cdots v_n$ be a Hamiltonian path in G , then $v_1 \not\sim v_n$. Since $d_G(v_1) + d_G(v_n) \geq n$, by Pigeonhole Principle there are $v_i, v_{i+1} \in V(P) - \{v_1, v_n\}$ such that $v_{i+1} \sim v_1$ and $v_i \sim v_n$, and so we can obtain a Hamiltonian cycle.

We can prove a bit more based on the previous results. First, we introduce the notion of a *Hamiltonian closure*.

Definition 6.2.10 ▶ Hamiltonian Closure

For any graph G , the **Hamiltonian closure** of G , denoted by $\text{Cl}(G)$, is the graph with

$$V(\text{Cl}(G)) := V(G), \quad E(\text{Cl}(G)) := E(G) \cup \{uv \notin E(G) : d_G(u) + d_G(v) \geq v(G)\}.$$

Note that $\text{Cl}(G)$ is obtained by repeatedly joining vertices in G with degree sum at least the order of G until no more edge can be added. The following result establish a connection between Hamiltonicity of a graph and its closure.

Proposition 6.2.11 ▶ Characterisation of Hamiltonian Graph with Closure

A graph G is Hamiltonian if and only if $\text{Cl}(G)$ is Hamiltonian.

Proof. If G is Hamiltonian, then it is trivial that $\text{Cl}(G)$ is Hamiltonian. Suppose conversely that $\text{Cl}(G)$ is Hamiltonian and suppose on contrary that G is not Hamiltonian, then there exists some graph H with $V(H) = V(G)$ and $E(G) \subseteq E(H)$ such that H is not Hamiltonian but $H + uv$ is Hamiltonian for some $u \sim v$ with $d_H(u) + d_H(v) \geq v(H)$ in H . Notice that the Hamiltonian cycle in $H + uv$ must contain the edge uv because otherwise H is also Hamiltonian, and so H must contain a Hamiltonian u - v path. However, this implies that we can find a Hamiltonian cycle in H containing u and v , which is a contradiction. Therefore G must be Hamiltonian. \square

Recall that if a graph G has low independence number, $\chi(G) \geq \frac{v(G)}{\alpha(G)}$ is large. By Proposition 4.1.8, this means that G contains a $\chi(G)$ -critical graph with high minimum degree. If this minimum degree is large enough, we get a large cycle in the subgraph. Suppose we additionally ensure that the graph is connected, then a Hamiltonian cycle is expected.

Theorem 6.2.12 ▶ Chvátal-Erdős Theorem

A graph G with at least 3 vertices is Hamiltonian if $\kappa(G) \geq \alpha(G)$.

Proof. Let $C := v_1v_2 \cdots v_n$ be the longest cycle in G . We claim that C is Hamiltonian. Suppose on contrary that C is not Hamiltonian, then there exists some vertex $v \in V(G) - V(C)$. Define \mathcal{F} to be the maximal set of vertex-disjoint paths from v to the vertices in C . By Theorem 3.3.13, $|\mathcal{F}| = \min\{\kappa(G), n\}$. For every $v_i \in V(C)$ such that there is a v - v_i path in \mathcal{F} , notice that there is no v_{i+1} - v path in \mathcal{F} because otherwise we can obtain a larger cycle including v . Therefore, $|\mathcal{F}| < n$ and so $|\mathcal{F}| \geq \kappa(G) \geq \alpha(G)$. For any $v_i, v_j \in V(C)$ with $i < j$ such that \mathcal{F} contains a v - v_i path P_i and a v - v_j path P_j , we claim that $v_{i+i} \sim v_{j+1}$ because otherwise

$$(C - v_iv_{i+1} - v_jv_{j+1} + v_{i+1}v_{j+1}) \cup P_i \cup P_j$$

is a larger cycle. Let I be an index set such that $\{v_{I(1)}, v_{I(2)}, \dots, v_{I(k)}\}$ are k vertices such that there is a $v_{I(i)}-v$ path in \mathcal{F} , then $\{v_{I(1)+1}, v_{I(2)+1}, \dots, v_{I(k)+1}\}$ are k pair-wise non-adjacent vertices in C . Note that none of these vertices is adjacent to v and $k \geq \alpha(G)$, so

$$\{v_{I(1)+1}, v_{I(2)+1}, \dots, v_{I(k)+1}\} \cup \{v\}$$

is an independent set with at least $(\alpha(G) + 1)$ vertices, which is a contradiction. \square

There are a few other interesting properties of a graph to make it Hamiltonian. For instance, we have the following characterisation of regular Hamiltonian graphs:

Proposition 6.2.13 ▶ Sufficient Condition for Regular Graphs to Be Hamiltonian

Every 2-connected k -regular graph of order at most $3k$ is Hamiltonian.

Actually, people have studied k -regular graphs intensively to discover that there are infinitely many k -regular Hamiltonian graphs — actually the proportion of regular Hamiltonian graphs is so high that almost all regular graphs are Hamiltonian if we take a very large sample of regular graphs.

Theorem 6.2.14 ▶ Robinson-Wormald Theorem

Let $k \geq 3$ be an integer. For any n k -regular graphs, let $h(n)$ denote the number of Hamiltonian graphs in them, then

$$\lim_{n \rightarrow \infty} \frac{h(n)}{n} = 1.$$

A nice related result to this is that almost all k -regular bipartite graphs are Hamiltonian and k -colourable. For regular graphs with odd degrees, there is a stronger result to characterise their structures.

Theorem 6.2.15 ▶ Smith's Theorem

If G is a d -regular graph where d is odd, then for any $e \in E(G)$, there is an even number of Hamiltonian cycles in G containing e .

Proof. If there is no Hamiltonian cycle in G which contains e , then the statement is obviously true. Otherwise, Let $v \in e$ be a vertex to which e is incident, then there must be some Hamiltonian path in G that ends at v and contains e . Let \mathcal{H} be a graph such that $V(\mathcal{H})$ is the set of all Hamiltonian paths in G which end at v and contains e . For each $P \in V(\mathcal{H})$, write $P := vu_1u_2 \dots u_k$. If there is some $u_i \in V(P) - \{u_k, u_{k-1}, v\}$ such that $u_iu_k \in E(G)$, then $Q := vu_1u_2 \dots u_iu_ku_{k-1} \dots u_{i+1}$ is a unique Hamiltonian

path different from P in $P + u_i u_k$. Clearly, $Q \in V(\mathcal{H})$ and we define $PQ \in E(\mathcal{H})$. Notice that

$$d_{\mathcal{H}}(P) = \begin{cases} d_G(u_k) - 2 & \text{if } u_k v \in E(G) \\ d_G(u_k) - 1 & \text{otherwise} \end{cases}.$$

Let $C \subseteq G$ be a Hamiltonian cycle in G containing e and let $uv \in E(C) - \{e\}$, then clearly $C - uv$ is a vertex in \mathcal{H} such that $d_{\mathcal{H}}(C - uv) = d_G(u) - 2$, which is odd. However, by Lemma 1.1.7, the number of vertices in \mathcal{H} with odd degrees must be even, so there must be an even number of Hamiltonian cycles in G containing e . \square

A very interesting corollary of Theorem 6.2.15 states that every Hamiltonian 3-regular graph contains at least 3 Hamiltonian cycles.

Corollary 6.2.16 ► Property of Hamiltonian Cubic Graphs

Every cubic Hamiltonian graph contains at least 3 Hamiltonian cycles.

Proof. Let G be a Hamiltonian 3-regular graphs. Fix a Hamiltonian cycle $C_1 \subseteq G$ and take any $e \in E(C_1)$. By Theorem 6.2.15, there is a distinct Hamiltonian cycle $C_2 \subseteq G$ such that $e \in E(C_2)$. Notice that $E(C_1) - E(C_2) \neq \emptyset$ because $C_1 \neq C_2$, so there exists at least one $e' \in E(C_1)$ with $e' \neq e$. Since $e' \notin E(C_2)$, by Theorem 6.2.15, there exists at least one Hamiltonian cycle $C_3 \neq C_2, C_1$ such that $e' \in E(C_3)$. Therefore, G contains at least 3 Hamiltonian cycles. \square

Recall that in Definition 1.1.19, we discuss the properties of an integer sequence for it to be the degree sequence of some graph. Now, we introduce a stronger definition.

Definition 6.2.17 ► Hamiltonian Sequence

A sequence (a_1, a_2, \dots, a_n) with $a_i \leq a_j$ for all $i \leq j$ is said to be a **Hamiltonian sequence** if every graph with degree sequence (d_1, d_2, \dots, d_n) such that $d_i \geq a_i$ for all $i = 1, 2, \dots, n$ is Hamiltonian.

Clearly by Theorem 6.2.6, the sequence $(\frac{n}{2}, \frac{n}{2}, \dots, \frac{n}{2})$ of length n is Hamiltonian for every integer $n > 2$. The following theorem, however, allows us to characterise all Hamiltonian sequences:

Theorem 6.2.18 ► Chvátal's Hamiltonian Sequence Theorem

For $n \geq 3$, an integer sequence (a_1, a_2, \dots, a_n) with $a_i \leq a_j$ for all $i \leq j$ is Hamiltonian if and only if for every $i < \frac{n}{2}$, $a_i \leq i$ implies $a_{n-i} \geq n - i$.

Proof. Suppose that (a_1, a_2, \dots, a_n) is an integer sequence with $a_i \leq a_j$ for all $i \leq j$ such that $a_i \leq i$ implies $a_{n-i} \geq n - i$. We claim that for any graph G with degree sequence (d_1, d_2, \dots, d_n) such that $d_i \geq a_i$ for all $i = 1, 2, \dots, n$, $\text{Cl}(G)$ is complete. Suppose on contrary that there exists some graph G satisfying the degree condition but $\text{Cl}(G)$ is not complete. Without loss of generality, take G to be the edge-maximal graph such that this occurs. Notice that $G = \text{Cl}(G)$, because otherwise $\text{Cl}(G)$ is a graph with strictly more edges than G satisfying the conditions, but $\text{Cl}(\text{Cl}(G)) = \text{Cl}(G)$ is not complete, which is not possible by maximality of G . Therefore, for every $u, v \in V(G)$ with $u \not\sim v$, we must have $d_G(u) + d_G(v) \leq n - 1$. Without loss of generality, take u, v such that $d_G(u) + d_G(v)$ is maximised and $d_G(u) \leq d_G(v)$. Notice that $d_G(u) < \frac{n}{2}$. Define $i := d_G(u)$, then $d_G(v) \leq n - i - 1$. Define

$$\overline{V} := V(G) - N_G(v),$$

then $|\overline{V}| \geq i$ and for every $w \in \overline{V}$,

$$d_G(w) \leq d_G(u) < \frac{n}{2}$$

because otherwise $d_G(u) + d_G(v)$ is not maximised. This implies that at least i vertices have degrees at most i in G , and so $d_i \leq i$, which means that $a_i \leq d_i \leq i$. Similarly, there are exactly $(n - i - 1)$ vertices in G which are non-adjacent to u and each of them has a degree of at most $n - i - 1$. Note that $d_G(u) \leq n - i - 1$, so there are at least $(n - i)$ vertices in G with degrees at most $n - i - 1$, and so $d_{n-i} \leq n - i - 1$. However,

$$d_{n-i} \geq a_{n-i} \geq n - i > n - i - 1,$$

which is a contradiction. Therefore, $\text{Cl}(G)$ is complete and thus Hamiltonian, which implies that G is also Hamiltonian by Proposition 6.2.11.

Suppose conversely that a non-decreasing integer sequence (a_1, a_2, \dots, a_n) is Hamiltonian, then we shall prove that $i < \frac{n}{2}$ implies that $a_{n-i} \geq n - i$ by considering the contrapositive statement. Suppose that there is some $i < \frac{n}{2}$ such that $a_i \leq i$ but $a_{n-i} < n - i$. Notice that this means that $a_j \leq i$ for all $j \leq i$, $i \leq a_j \leq n - i - 1$ for all $i < j \leq n - i$. Construct a graph G as follows: take a complete graph K_{n-i} and fix any set of i vertices from K_{n-i} , denoted as V . Let U be a copy of V and construct a complete bipartite graph $K_{i,i}$ on U and V . Notice that G has degree sequence $\{d_j\}_{j=1}^n$

such that

$$d_j = \begin{cases} i & \text{if } 1 \leq j \leq i \\ n - i - 1 & \text{if } i + 1 \leq j \leq n - i \\ n - 1 & \text{if } n - i + 1 \leq j \leq n \end{cases}.$$

Notice that $d_j \geq a_j$ for all $j = 1, 2, \dots, n$, but $G - V$ has $(|V| + 1)$ connected components, so G is not Hamiltonian by Proposition 6.2.5. Therefore, (a_1, a_2, \dots, a_n) is not a Hamiltonian sequence. \square

Remark. Note that Theorem 6.2.18 only provides a sufficient condition to construct the degree sequence of a Hamiltonian graph, but the degree sequence of a Hamiltonian itself might not be a Hamiltonian sequence!

Using a similar approach, one can prove the following result:

Theorem 6.2.19 ► Condition of a Path-Hamiltonian Sequence

An integer sequence $\{a_i\}_{i=1}^n := (a_1, a_2, \dots, a_n)$ is such that every graph with a degree sequence element-wise greater than or equal to $\{a_i\}_{i=1}^n$ contains a Hamiltonian path if and only if for every $i \leq \frac{n}{2}$, $a_i < i$ implies $a_{n+1-i} \geq n - i$.

6.3 Vertex-Transitive Graph

Some well-known conjectures regarding Hamiltonian graphs relate Hamiltonicity to the symmetry of a graph. Here we first define a way to describe the symmetric-ness of a graph.

Definition 6.3.1 ► Vertex-Transitive Graph

A graph G is said to be **vertex-transitive** if for every $v_1, v_2 \in V(G)$, there exists some isomorphism $f : V(G) \rightarrow V(G)$ such that $f(v_1) = v_2$.

Despite many conjectures, there have not been many easy results proved in the study of Hamiltonicity of vertex-transitive graphs. However, in a weaker area, one can try to bound the size of the longest cycle in a vertex-transitive graph.

Theorem 6.3.2 ► Babai's Theorem

Every connected vertex-transitive graph G contains a cycle of length at least $\sqrt{3n}$.

This bound has been improved to $(1 - o(1))n^{\frac{3}{5}}$ in 2023.

Directed Graph

In previous chapters, we have been dealing with undirected graphs mainly. However, there are many scenarios where a directed graph is more useful. One such example is the study of network flow problems where the flow is directed between a pair of nodes.

7.1 Directed Graph

Definition 7.1.1 ► Directed Graph

A **directed graph** D , or **digraph** for short, consists of a vertex set $V(D)$ and an edge set $E(D)$ defined as a set of ordered pairs (u, v) for some $u, v \in V(D)$.

Usually, we denote a directed edge as $u \rightarrow v$ to indicate the edge's orientation. We say that u is a *predecessor* of v and v is a *successor* of u . Note that an undirected graph is then equivalent to a digraph where each pair of vertices have a pair of bi-directional edges. A special type of digraphs require that no bi-directional edges can exist.

Definition 7.1.2 ► Oriented Graph

An **oriented graph** D is a digraph such that for every $u \rightarrow v \in E(D)$, $v \rightarrow u \notin E(D)$.

We now introduce some terminologies. First, for a *directed cycle* of size n , we denote such a cycle as \vec{C}_n . An edge $u \rightarrow v$ is known as an *in-edge* at u and *out-edge* at v . The numbers of in-edges and out-edges at a vertex v are known as the *in-degree* and *out-degree* of v , denoted by $d^-(v)$ and $d^+(v)$ respectively. In particular, denote

$$N^+(v) := \{u \in V(D) : vu \in E(D)\}, \quad N^-(v) := \{u \in V(D) : uv \in E(D)\}.$$

Intuitively, the sum of in-degrees in a digraph must equal the sum of out-degrees over all vertices, so we have the following proposition equivalent to the Handshaking Lemma:

Proposition 7.1.3 ▶ Sum of Degrees in Digraphs

Let D be a digraph, then

$$\sum_{v \in V(D)} d^+(v) = \sum_{v \in V(D)} d^-(v) = e(D).$$

Many results in undirected graphs can be generalised to directed cases. For example, in Theorem 6.1.2, we states that a connected undirected graph is Eulerian if and only if every vertex has an even degree. However, in the directed case, it is easy to see that in order to use every edge in a digraph, for any vertex v , every time we visit v via an in-edge, we have to leave v via an unvisited out-edge. Therefore, the fact that having even degrees for all vertices guarantees a Eulerian graph is a direct result of the following statement:

Proposition 7.1.4 ▶ Necessary and Sufficient Condition for Eulerian Digraphs

A digraph D is Eulerian if and only if for every $v \in V(D)$, we have $d^+(v) = d^-(v)$.

Next, let us see how we can define connectivity in the directed case. For simplicity, let us define the underlying undirected graph of a digraph D as a graph G with $V(G) = V(D)$ and $E(G)$ obtained by joining every pair of vertices that are connected via any one directed edge in D . If G is connected, then D is “connected” in a sense that no vertex is isolated.

Definition 7.1.5 ▶ Weak Connectivity

A digraph D is **weakly connected** if its underlying undirected graph is connected.

However, note that in a weakly connected digraph D , having no isolated vertex does not guarantee that there is always a path from any $u \in V(D)$ to any $v \in V(D)$. Consider a directed u - v path, then it is clearly weakly connected but we can only traverse from u to v but not the other way around. Therefore, the “complete” connectivity is a much stronger property in digraphs.

Definition 7.1.6 ▶ Strong Connectivity

A digraph D is **strongly connected** if for every $u, v \in V(D)$, there is a directed u - v path in D . A maximal strongly connected subgraph of D is known as a **strongly connected component** of D .

Recall that in undirected graphs, we define an independent set to be a subset of vertices that induces no edges. A similar structure can be defined on digraphs.

Definition 7.1.7 ▶ Kernel

Let D be a digraph. A **kernel** of D is a set $S \subseteq V(D)$ such that for any $u, v \in S$, $uv, vu \notin E(D)$ and for any $w \in V(D) - S$, there is some $w' \in S$ with $ww' \in E(D)$.

It might be useful to view a kernel as the “core” of a digraph such that every vertex outside of it points to something in it. Note that unlike independent set, not every digraph has a kernel. The easiest example is \vec{C}_3 . In fact, with some observations we can prove the following result:

Proposition 7.1.8 ▶ Odd Directed Cycles Have No Kernel

Any directed cycle \vec{C}_{2k+1} for $k \in \mathbb{Z}^+$ has no kernel.

Proof. Suppose on contrary that there is some $k \in \mathbb{Z}^+$ such that $K \subseteq V(\vec{C}_{2k+1})$ is a kernel. Clearly, $|K| \leq \alpha(C_{2k+1}) = k$. Define $\bar{K} := V(\vec{C}_{2k+1}) - K$, then

$$|\bar{K}| \geq 2k + 1 - k = k + 1 > |K|.$$

However, every $v \in \bar{K}$ must have a distinct out-neighbour $u \in K$, which is a contradiction. \square

The above proposition turns out to be important for characterisation of kernel-free digraphs.

Theorem 7.1.9 ▶ Richardson’s Theorem

If a digraph D does not contain any directed odd cycle, then D has a kernel.

Proof. If D is strongly connected, we can a vertex $y \in D$ and for every $v \in V(D) - \{y\}$, there is a directed v - y path in D . Define

$$S := \{v \in V(D) : d_D(v, y) \text{ is even}\}.$$

We claim that S induces no edge in D . Suppose on contrary that there is some edge $uv \in E(D)$ with $u, v \in S$. Note that there is some even u - y path P and some even v - y path P' in D , so $uv + P'$ is an odd path and so $uv + P' \neq P$. Since D is strongly connected, there is some y - u path Q in D . Notice that now, $P' \cup Q \cup \{uv\}$ and $P \cup Q$ are two distinct closed walks in D with lengths $e(P') + e(Q) + 1$ and $e(P) + e(Q)$ respectively. Note that $e(P')$ and $e(P)$ are even, so the sizes of the two closed walks have different parity. Therefore, at least one of them is an odd closed walk and so contains a directed odd cycle, which is a contradiction.

For every $u \in V(D) - S$, we know that there is a u - y path with odd length. Let w be the successor of u along the path, then $d_D(w, y)$ is even and so $w \in S$. Since $uw \in E(D)$, this implies that S is a kernel of D .

If D is not strongly connected, we shall apply strong induction on $v(D)$. The case where D is of order 2 is trivial. Now, suppose that any digraph containing no directed odd cycle with orders less than D has a kernel. Take D' to be a strongly connected component in D . By the previous argument, D' has a kernel S' . If for all $v \in D - D'$, v is a successor to some vertex in S' , then S' is a kernel of D . Otherwise, let D'' be a subgraph of $D - D'$ obtained by deleting all successors to vertices in S' . D'' has a kernel S'' by the inductive hypothesis. Clearly, $S' \cup S''$ is a kernel in D . \square

7.2 Tournament

A special type of digraphs is *tournament*, which is the counterpart of complete graphs in digraphs.

Definition 7.2.1 ▶ Tournament

A **tournament** T is a digraph such that the graph G defined by

$$V(G) := V(T), \quad E(G) := \{uv : u \rightarrow v \in E(T) \text{ or } v \rightarrow u \in E(T)\}$$

is complete.

Although it may sound counter-intuitive, we can actually prove that any tournament contains a Hamiltonian path.

Proposition 7.2.2 ▶ Existence of Hamiltonian Paths in Tournaments

Any tournament contains a Hamiltonian path.

Proof. Suppose on contrary that there exists some tournament T without any Hamiltonian path. Take $P := v_1 v_2 \cdots v_n$ to be a longest path in T . Since P is not Hamiltonian, there exists some $u \in V(T) - V(P)$. Notice that $v_n \rightarrow u, u \rightarrow v_1 \notin E(T)$, so $u \rightarrow v_n, v_1 \rightarrow u \in E(T)$. Therefore, it is clear that there must exist some integer $i \in [1, n-1]$ such that $v_i \rightarrow u, u \rightarrow v_{i+1} \in E(T)$. However, this means that $v_1 \cdots v_i u v_{i+1} \cdots v_n$ is a longer path in T , which is a contradiction. \square

Just like undirected graphs, we say that a tournament T_n is *acyclic* if it contains no directed

cycle. Alternatively, we also call it a *transitive* tournament.

Proposition 7.2.3 ► Characterisation of Transitive Tournaments

A tournament T is transitive if and only if there exists a labelling of its vertices into v_1, v_2, \dots, v_n such that $v_i \rightarrow v_j \in E(T)$ for every $i < j$.

Proof. If there exists such a labelling, then clearly every path in T is in the form of $v_{I(1)}v_{I(2)} \cdots v_{I(k)}$ for some index set $I \subseteq \{1, 2, \dots, n\}$ such that $I(i) < I(j)$ for every $i < j$. Note that $v_{I(k)} \rightarrow v_{I(1)} \notin E(T)$, so T does not contain any cycle.

Suppose conversely that T is transitive. Consider the following lemma:

Lemma 7.2.4 ► Acyclic Graphs Contain Vertices without Incoming Edges

For any acyclic digraph G , there exists some vertex $v \in V(G)$ such that $d_G^-(v) = 0$.

Proof. We shall prove the contrapositive statement. Suppose that for every $v \in V(G)$, we have $d^-(v) \geq 1$. Fix some $v_1 \in V(G)$, then there exists some $v_2 \in V(G)$ such that $v_2 \rightarrow v_1 \in E(G)$. Continuing taking vertices this way, since the graph is finite, we will eventually reach a vertex $v_k \in V(G)$ such that for all $v_i \in N_G^-(v_k)$, we have $i < k$. Take any v_i with $v_i \rightarrow v_k \in E(G)$, then since $v_kv_{k-1} \cdots v_i$ is a path, we have obtained a directed cycle in G . \square

By Lemma 7.2.4, there exists some $v_1 \in V(T)$ with no incoming edge, so no matter how the other vertices are labelled, $v_1 \rightarrow v_i \in E(T)$ for all $i > 1$. Now, suppose we have fixed the labelling up to v_k , then $T - \{v_1, v_2, \dots, v_k\}$ is still an acyclic tournament and so there exists some v_{k+1} with no incoming edge. Therefore, we can eventually reach a labelling where $v_i \rightarrow v_j$ is an edge for every $i < j$. \square

In fact, such labelling can be generalised to any acyclic directed graph.

Definition 7.2.5 ► Topological Ordering

Let G be a directed graph, a **topological ordering** is a map

$$f : V(G) \rightarrow \{1, 2, \dots, v(G)\}$$

such that if $u \rightarrow v \in E(G)$, then $f(u) < f(v)$.

Remark. A digraph has a topological ordering if and only if it is acyclic.

Using some easy constructions, it is easy to show that Hamiltonian paths in a tournament

might not be unique. However, the following result states a condition for such Hamiltonian path to be unique:

Proposition 7.2.6 ▶ Transitive Tournament Has a Unique Hamiltonian Path

A tournament contains a unique Hamiltonian path if and only if it is transitive.

Proof. Let T be a transitive tournament. By Proposition 7.2.2, the existence is guaranteed. By Proposition 7.2.3, fix a topological ordering v_1, v_2, \dots, v_n in T . Since $v_i \rightarrow v_j$ is an edge only when $i < j$, then only possible Hamiltonian path is $v_1 v_2 \dots v_n$.

Suppose conversely that a tournament T contains a unique Hamiltonian path. Denote the path by $v_1 v_2 \dots v_n$. We claim that this path induces a topological ordering in T . Suppose on contrary that there is some $v_p \in V(T)$ such that $v_k \rightarrow v_p \in E(T)$ for some $k > p$ and let v_q be the last vertex such that $v_q \rightarrow v_p \in E(T)$. Without loss of generality, let v_p be the first such vertex. If $p \neq 1$ and $q \neq n$, then $v_{p-1} \rightarrow v_{p+1} \in E(T)$. By the maximality of q , we have $v_m v_{q+1} \in E(T)$, which implies that $v_1 v_2 \dots v_{p-1} v_{p+1} v_{p+2} \dots v_q v_p v_{q+1} v_{q+2} \dots v_n$ is a different Hamiltonian path. One may check that for the cases where $p = 1$ or $q = n$, we can also find a different Hamiltonian path in T , which is a contradiction. \square

In another direction, we can also characterise the structure of a non-transitive tournament.

Proposition 7.2.7 ▶ Non-transitive Tournaments Contain Directed Triangles

Any tournament which is not transitive contains some directed triangle.

Proof. Let T be a tournament which is not transitive and let $\vec{C}_k := v_1 v_2 \dots v_k v_1$ be the shortest directed cycle in T . If $k = 3$, then we are done. Otherwise, $k > 3$. Notice that $v_{k-1} \rightarrow v_1 \notin E(T)$ because otherwise there is a shorter directed cycle. Therefore, $v_1 \rightarrow v_{k-1} \in E(T)$, and so $v_1 v_{k-1} v_k v_1$ is a directed triangle. \square

Note that the existence of Hamiltonian paths in tournaments guarantees that there is always a vertex which is reachable from any other vertex in a tournament. However, to reach this “end” vertex, it might not give the shortest path along the Hamiltonian path. Thus, we might wish to further strengthen this result.

Definition 7.2.8 ▶ King

Let T be a tournament, a vertex $k \in T$ is said to be a **king** of T if for every $v \in V(T)$, there is a directed v - k path of length at most 2.

Surprisingly, we always get a king in any tournament for free.

Theorem 7.2.9 ► Landau's Theorem

Every tournament has a king.

Proof. Suppose on contrary that there exists some tournament T which does not contain a king. Take $v \in V(T)$ to be the vertex with the largest in-degree. Since v is not a king, there must exist some $u \in V(T)$ such that there is no directed u - v path of length at most 2 in T . Therefore, $v \rightarrow u \in E(T)$ and for every $w \in N_T^-(v)$, we must have $w \rightarrow u \in E(T)$. This means that $N_T^-(u) \subseteq N_T^-(v) \cup \{v\}$, and so $d_T^-(u) > d_T^-(v)$, which is a contradiction. \square

Note that although the existence of a king is guaranteed in any tournament, the uniqueness is not. The following definition generalises the concept of a king:

Definition 7.2.10 ► Quasi-kernel

Let D be a digraph. A **quasi-kernel** of D is a set $S \subseteq V(D)$ such that for every $u \in V(D) - S$, there is a directed u - v path for some $v \in S$ of length at most 2.

Clearly, a king in a tournament is always a vertex in the quasi-kernel. However, the existence of a quasi-kernel is also guaranteed for any digraph.

Theorem 7.2.11 ► Chvátal-Lovász Quasi-kernel Existence Theorem

Every digraph D has a quasi-kernel.

Proof. We shall apply strong induction on $|V(D)|$. The case where $|V(D)| = 1$ is trivial because D is its own quasi-kernel. Suppose that there exists some integer $n \geq 1$ such that any digraph with order less than n has a quasi-kernel. Take any $v \in V(D)$. If $\{v\} \cup N_D^-(v) = V(D)$, then $\{v\}$ is a quasi-kernel. Otherwise, define

$$D' := D - (\{v\} \cup N_D^-(v)).$$

By the inductive hypothesis, D' has a quasi-kernel S . If $S \cap N_D^+(v) = \emptyset$, then $S \cup \{v\}$ is a quasi-kernel in D . Otherwise, there is some $s \in S$ such that $v \rightarrow s \in E(D)$. This means that S is a quasi-kernel in D because every $u \in N_D^-(v)$ has a directed path of length 2 to s . Therefore, any digraph always has a quasi-kernel. \square
